ABSTRACT

This thesis treats of the morphophonology of verbal stress in A'ingae (Cofán, ISO 639-3: con), an isolate language of the Amazon. By presenting and generalizing over novel data, it makes contributions to language description, typology, and theory.

At the level of description, it demonstrates sensitivity of stress to weight, systematizes the template of verbal inflections, and details its intricate patterns of morphophonological alternations.

At the level of typology, it observes a rare, if not unattested, accentual pattern, whereby the primary stress targets the syllable containing the second mora to the left of a glottal stop.

At the level of theory, it constructs an account within the framework of Cophonology (Anttila, 1997a; Orgun, 1996; others) and lends support to the framework by dint of its analytical parsimony.

ACKNOWLEDGEMENTS

First and foremost, I have to thank my research advisor, Dr. Scott AnderBois. Without his assistance and dedicated involvement throughout the process, my thesis could have never been completed. I would like to thank you very much for your support and understanding over these past four years.

My sincere thanks goes to all my linguistic professors, who nourished my intellectual passions, and in particular to Dr. Uriel Cohen Priva and Dr. Roman Feiman, whose academic guidance and made a better scholar, even if ever so slightly.

I would like to thank all others who provided me with feedback on my work. Thanks to Kalinda Pride for her input and acute insight.

Crucially, I would like to show gratitude to all my Cofán collaborators for the kindness and generosity they treated me with. Their willingness to share their language, culture, and homesteads with me made this work possible.

In particular, I would like to thank Hugo Lucitante, my friend and first Cofán collaborator, who showed me the beauty of his native language language, introduced me to the Cofán communities, and guided me as my interest in A'ingae deepened and matured.

I would like express my gratitude to the communities of Dureno and Singangoé, who welcomed and accommodated me. In particular, I would like to say thank you to the family of Jorge Criollo, who hosted me for three weeks and tolerated my daybreak *yuku* excursions.

I thank Shen Aguinda and Leidy Quenamá, my two research assistance who graciously spent long hours thinking carefully about the data and ideas discussed here.

I thank the Cofán men who evacuated me out Sinangoé in a canoe at night during a flood.

Last but not least, I would like to thank my family who supported me spiritually throughout my life. Thank you, mom, for giving birth to me and always being there for me.

INTRODUCTION

The subject matter of this work is the rich morphophonology of verbal stress in A'ingae (Cofán, ISO 639-3: con), a language isolate of the Amazon. It will present novel data and advance original generalizations, contributing to language description, typology, and theory.

I will systematize the inflectional template the A'ingae verb and detail the morphophonological alternations found within it.

Furthermore, I will demonstrate the sensitivity of A'ingae stress assignment to syllabic weight as well as the presence of glottal stops, which cannot be accounted for with the notion of syllabic weight.

Finally, I will lend support to the framework of Cophonology Theory (Anttila, 1997a; Orgun, 1996; others) by providing a parsimonious Cophonological account of the complex data.

1.1 THE PUZZLE

A'ingae's complex stress system is highly complex. It can be thought of as presenting two interwoven challenges, one morphological and one phonological.

The morphological challenge is posed by the descriptive necessity to posit the existence of six different suffix types, each associated with a separate accentual pattern. This can be demonstrated by a minimal six-tuple of pairs of verbs inflected with a suffix of each type and another suffix to its right (1-6), here exemplified with the verbs *upathû* 'pick' and *afase* 'insult' and the negative suffix *-mbi* 'NEG.' Stress is marked with the acute accent and an underline.

		a. <i>upathû ...-mbi</i> 'pick ...-NEG'	b. <i>afase ...-mbi</i> 'insult ...-NEG'
(1)	<i>-'chu</i>	'SBRD'	<i>upáthû-'chu-mbi</i> <i>áfase-chu-mbi</i>
(2)	<i>-'fa</i>	'PLS'	<i>upathû-'fa-mbi</i> <i>áfase-fa-mbi</i>
(3)	<i>-ji</i>	'PRCM'	<i>upathû-jí-mbi</i> <i>áfase-ji-mbi</i>
(4)	<i>-'je</i>	'IMPV'	<i>upáthû-'je-mbi</i> <i>afáse-'je-mbi</i>
(5)	<i>-'kha</i>	'DMN'	<i>upathû-'kha-mbi</i> <i>afasé-'kha-mbi</i>
(6)	<i>-khu</i>	'RCPR'	<i>upathû-khú-mbi</i> <i>afase-khú-mbi</i>

In forms of *upathû* ‘pick’ (1-6a), the subordinating –’chu ‘SBRD’ and the imperfective –’je ‘IMPV’ induce stem-penultimate stress (1, 4a), the plural subject –’fa ‘PLS’ and the verbal diminutive –’kha ‘DMN’ induce stem-ultimate stress (2, 5a), and the precumulative –ji ‘PRCM’ and the reciprocal –khu ‘RCPR’ induce post-stem stress (3, 6a). In forms of *afase* ‘offend’ (1-6b), only –’je ‘IMPV,’ –’kha ‘DMN,’ and –khu ‘RCPR’ induce the same patterns (4-6b), while –’chu ‘SBRD,’ –’fa ‘PLS,’ and –ji ‘PRCM’ occur with stem-initial stress (1-3b). Thus, six distinct accentual patterns are observed.

The phonological challenge consists of the peculiar role glottal stops play in stress assignment, as revealed in comparing stress induced by suffixes without glottal stops, such as –ji ‘PRCM’ (8), and with glottal stops, such as –’je ‘IMPV’ (9), on roots with syllables of different weights: light-light (7-9a), heavy-light (7-9b), and light-heavy (7-9c).

- | | | | |
|-----|------------------------------------|------------------------------------|--------------------------------------|
| (7) | a. <i>fétha</i>
‘open’ | b. <i>fúite</i>
‘help’ | c. <i>fíndúi</i>
‘sweep’ |
| (8) | a. <i>fethá-ji</i>
‘open-PRCM’ | b. <i>fúité-ji</i>
‘help-PRCM’ | c. <i>fíndúi-ji</i>
‘sweep-PRCM’ |
| (9) | a. <i>fétha-’je</i>
‘open-IMPV’ | b. <i>fúite-’je</i>
‘help-IMPV’ | c. <i>fíndúi-’je</i>
‘sweep-IMPV’ |

In the absence of a glottal stop, stress falls on the penultimate syllable (7-8). When a glottal stop is present, stress falls on the syllable with the second mora before the glottal stop (9). This results in stem-penultimate stress when the ultima is light (9a-b), and stem-ultimate stress when the ultima is heavy (9c). The accentual pattern observed in (7-9) is, to the best of my knowledge, typologically unattested.

1.2 ANALYTICAL PRÉCIS

The analysis of the A’ingae morphophonology in Chapter 4 will be couched in Cophonology Theory (Anttila, 1997a; Orgun, 1996; others), a framework which integrates phonology and morphology, providing formal tools for a rigorous and elegant account of complex interactions between the two. The phonological functions proposed as part of the Cophonological analysis will be stated within Optimality Theory (McCarthy and Prince, 1993; Prince and Smolensky, 1993; others), which views observed linguistic forms as maximally harmonic with respect to rankings of conflicting constraints. Many of the constraints will be formulated within the McCarthy and Prince (1993)’s framework of Generalized Alignment, which deals with reference to edges in morphology and phonology.

In the course of the analysis, I will distinguish between two classes of verbs, categorize suffixes with respect to two binary parameters, and capture the above glottal pattern with an ALIGNMENT constraint (McCarthy and Prince, 1993). Thus, I will reduce the observed complexity to a much smaller number of theoretical posits. I will further motivate my proposal by its ability to account for other yet-undiscussed morphophonological phenomena, such glottal stop deletion (1-2a).

My thesis is restricted in scope to verbal morphophonology. Although nominal morphophonology is dissimilar from verbal to some extent (Fischer and Hengeveld, *forthcoming*, henceforth F&H), verbal morphology is much richer, which compelled me to study it in greater depth.

1.3 ROAD MAP

The rest of [Chapter 1](#) provides a road map for the thesis. [Chapter 2](#) gives background on the language, including its geography, history, typology, current status, previous scholarship, segmental phonology, and phonetics of stress. [Chapter 3](#) introduces verbal morphology, motivates the refinements it proposes, and raises the question of clitichood in A'ingae. [Chapter 4](#) presents a Cophonological analysis of the A'ingae verb's metrical morphophonology. [Chapter 5](#) concludes.

BACKGROUND

The Cofán are an indigenous people of South America, presently inhabiting the northeast Ecuadorian province of Sucumbíos and in southern Colombia. Their origin can be traced back to the Andes. Historically, they made use of a large territory as a primarily hunter-gatherer people (Cepek, 2012). The map below gives their current geography (Curnow and Liddicoat, 1998).

Indigenous languages of southern Colombia and northern Ecuador.

The Cofán people speak *a'ingae*, which is to say: “like (civilized) people.” This endonym can be morphologically decomposed into *a'i* ‘(civilized) person’ and the manner case clitic *=ngae* ‘MANN.’ In linguistic literature, “Cofán” and “A'ingae” are used interchangeably to refer to the language.

A'ingae is an endangered, though robust, and severely underdocumented language isolate (F&H). Issues related to language status are

discusses in [Section 2.1](#). Notable scholarship on the language is listed in [Section 2.2](#), which also summarizes previous research on verbal morphology and lexical stress.

Although A'ingae is often placed in the Amazonian sprachbund, its Andean origin is reflected in the mixture of its prototypically Amazonian and Andean features (AnderBois, Emlen, Lucitante, Sanker, and Silva, [2019](#)). The typological profile of the language is briefly discussed in [Section 2.3](#).

Segmental phonology and a few major phonological processes are introduced in [Section 2.4](#). Lastly, [Section 2.5](#) outlines the phonetics and stress and glottal stops, which have a very prominent prosodic role.

Almost all of the data in the present work draw on elicitations conducted by the author with native speakers from three indigenous communities of Ecuador: Zábalo, Dureno, and Sinangoé. Thus, it should only be considered representative of the Ecuadorian language variety. Some of the data in [Chapter 3](#) comes from previously published sources; all of it is cited as such.

2.1 LANGUAGE STATUS

A'ingae has around 1 500 native speakers across Ecuador and Colombia (Repetti-Ludlow, Zhang, Lucitante, AnderBois, and Sanker, [2019](#)). Since the Cofán population nearly quintupled since the 1960s, the language is classified as developing (Eberhard, Simons, and Fennig, [2019](#)). In Ecuador, A'ingae is used vigorously. In communities with stronger Kichwa and colonial influences, especially in Colombia, the prominence of Spanish in everyday communication is elevated at the cost of A'ingae. The national borders demarcate a linguistic divide: of the two major dialects, one is spoken along the Aguarico River in Ecuador; the other—on the San Miguel, Guamués, and Putumayo rivers in Colombia (M. B. Borman, [1962](#)).

First orthography for the language was developed by Marlytte Bub Borman and Roberta Bobbie Borman, missionary linguists first active in the Cofán communities in 1950's. It was recently revised by members of the Cofán communities. The data in the current work is presented in the revised orthography. For comparisons of the two orthographies, see Fischer and Hengeveld ([forthcoming](#)) and Repetti-Ludlow et al. ([2019](#)).

An estimated two thirds of A'ingae speakers are literate in A'ingae as well as Spanish, which is the language of instruction in schools (Eberhard, Simons, and Fennig, [2019](#)).

2.2 PREVIOUS SCHOLARSHIP

There is little previous scholarship on the language. Outside of a few brief word lists, the first contributions to the systematic study of A'ingae were made by the Bormans, who provide the first and only substantial dictionary M. B. Borman (1976), and a collection of cosmological narratives M. B. Borman and Enrique Criollo (1990). Other notable works include a grammatical sketch by F&H, a collection of traditional stories by Blaser and Umenda (2008), and the scholarly output of the A'ingae Language Documentation Project, which includes, but is not limited to, AnderBois, Emlen, et al. (2019), AnderBois and Sanker (2019), AnderBois and Silva (2018), Dąbkowski (2019), Dąbkowski and AnderBois (*forthcoming*), Pride, Tomlin, and AnderBois (*forthcoming*), and Repetti-Ludlow et al. (2019).

2.2.1 *verbal morphology*

There have been significant treatments of the language's morphology. First discussion of verbal morphology appears in M. B. Borman (1976). A fuller morphological template is given by F&H, who pay close attention to the ordering and cooccurrence restrictions among the morphemes. I further revise the template in Chapter 3. Other work which touches on the verbal morphology, but is not immediately relevant the morphophonological concerns taken up here, includes Fischer (2007)'s treatment of clause linkage.

2.2.2 *stress and prosody*

Stress and prosody are among the lesser studied topics of this already understudied language. M. B. Borman (1962), Fischer and Hengeveld (*forthcoming*), and Repetti-Ludlow et al. (2019) provide phonetic and phonological descriptions of the language, though their treatment of stress is limited. AnderBois and Sanker (2019) focus on the issues of nasality, which have not been found to interact with stress.

With respect to lexical stress, M. B. Borman (1962) observes that stress falls usually on one of the first three syllables and is often penultimate. Furthermore, M. B. Borman (1976) reports that stress in words with glottal stops falls on the “penultimate syllable before the stop” (p. 3, translation mine), anticipating an important postulate of my analysis. M. B. Borman (1962) also identifies the existence of alternating secondary stress and recognizes the existence of “perturbations and variations in placement of stress” due to “morphophonemic

patters”—an analytical challenge he does not take up. On the whole, M. B. Borman (1962, 1976)’s generalizations find support in my data.

F&H observe that the addition of suffixes and clitics (which I reanalyze as suffixes in [Chapter 3](#)) does not change the position of stress and that in verbs stress is often ultimate. Thus, they largely contradict M. B. Borman (1962, 1976). On the whole, F&H generalizations do not find support in my data.

Repetti-Ludlow et al. (2019) observe that stress can be contrastive, and is never ultimate except for monosyllables. On the whole, Repetti-Ludlow et al. (2019)’s generalizations find support in my data.

Previous scholarship does not make systematic attempts to understand the interactions between morphology and phonology, nor does it recognize the role that syllabic weight plays therein. Therefore, all the generalizations I provide with respect to either are novel.

2.3 TYPOLOGICAL PROFILE

A’ingae is a head-final language, with SOV as a predominant word order. Subordinate clauses are strictly verb-final, while matrix clauses allows for various permutations, subject to pragmatic factors (F&H). Marking is found consistently on dependents, with verbal arguments carrying case clitics. The morphosyntactic alignment is nominative-accusative.

Verbal morphology is complex and encodes a large number of semantic categories, including valence, aspect, associated motion, subject person and number, polarity, switch-reference, information structure, various modalities, and others. The ordering of suffixes expressing these categories and the co-occurrence restrictions found among them are the subject of [Chapter 3](#).

A’ingae is spoken in a region located between the Andes and the Amazon. Historical and archaeological evidence shows movement of the Cofán people eastward over the course of several centuries. As such, one is not surprised to see a blend of typically Amazonian and Andean grammatical features. On the Andean side, A’ingae boasts a switch-reference system, an evidential marker, and an extensive case system. On the Amazonian side, A’ingae is employs a system of noun classifiers, a frustrative marker, and a lot of agglutination (AnderBois, Emlen, et al., 2019).

Sound inventory.

2.4 SEGMENTAL PHONOLOGY

This section will provide an introduction to the segmental phonology of the language. [Section 2.4.1](#) outlines the language's sound inventory and motivates major deviations from previous descriptions, mainly Repetti-Ludlow et al. (2019). The next two sections consider two groups of phonological rules particularly relevant to the data introduced in later chapters: [Section 2.4.2](#) gives an overview of nasality-related processes and [Section 2.4.3](#) details the changes that adjacent vowels undergo in order to form legal diphthongs.

2.4.1 *sound inventory*

A'ingae has a moderately large sound inventory, totalling twenty-seven consonants, ten vowels (split evenly between oral and nasal), and fifteen diphthongs (eight oral and seven nasal). The entire sound inventory is given on the following page, along with the most common graphemes associated with each phoneme. Deviations are associated with the application of phonological rules discussed in [Section 2.4.2](#) and [2.4.3](#), variously reflected in the orthography.

A characteristic feature of A'ingae's is the three-way distinction between plain (voiceless), aspirated, and prenasalized oral occlusives (F&H). Aspiration is common in the Andes, while prenasalization—in the Amazon basin. A'ingae has palatal sonorants, typical of the Andean group, but it has only one liquid consonant, as do language in the Amazonian sprachbund (AnderBois, Emlen, et al., 2019).

The language's five-vowel inventory with a high-central vowel is typically Amazonian (Aikhenvald, 2012). Thus, the distinction between its two back close vowels can be viewed as based in roundedness, rather than height. The unrounded back vowel's phonetic realization ranges from central to back, and the rounded one's from high to mid. Each oral vowel has a nasal counterpart.

The diphthong inventory proposed here, with eight oral and seven nasal diphthongs is larger from that of Repetti-Ludlow et al. (2019). In addition to the six oral and six nasal diphthongs they recognize, I include *ia* /ia/, *ian* /iã/ and the marginal diphthong *ae* /æ/.

The decision to include *ia* /ia/ and *ian* /iã/ among diphthongs has phonological motivations: for purposes of stress assignment, they pattern with other diphthongs. For example, the stress shift between (10a) and (10b) is predicted if (10a) is disyllabic, but unexpected if it were trisyllabic. This differs from the proposal of Repetti-Ludlow et al. (2019), who treat *ia*, *ian* /ia, iã/ as realized with an intervening

glide [i̯ja, i̯jā] and posit an optional deletion of the preconsonantal vowel, resulting in homosyllabic [ja, jā].

- | | |
|-------------------------|-----------------------|
| (10) a. <i>ámp̥hian</i> | b. <i>amphián-mbi</i> |
| 'drop' | 'drop-NEG' |

The decision to consider *ae /æ/* a marginal diphthong is motivated by the phonetic realization of the manner case clitic =*ngae* 'MANN.' Although Repetti-Ludlow et al. (2019) correctly observe that the orthographic *ai* and *ae* are both consistently realized as [ai] (more on which in [Section 2.4.3](#)), =*ngae* 'MANN' is a curious exception. The orthographic *ae* in =*ngae* 'MANN' has a distinct realization, which I transcribe broadly as /æ/, although its actual realization is unstable and ranges from [əæ] to [ɛ]. The marginal diphthong *ae /æ/* has not been observed in environments other than =*ngae* 'MANN.'

A'ingae syllable structure is (C)V(V)(?). Monophthongal nuclei make for monomoraic syllables; diphthongal nuclei make for bimoraic syllables. The glottal stop does not contribute to weight at the foot level, but attracts stress to the syllable which contains the second mora to its left. This pattern is discussed in detail in [Section 4.5](#).

2.4.2 *nasal processes*

Nasality-related phonological processes are likely among the most the most prominent in the language. They are, at the same time, some of the more complex processes to have been identified. They have been discussed extensively in AnderBois and Sanker (2019) and more briefly in F&H and Repetti-Ludlow et al. (2019). Since they affect verbal forms central to Chapters 3 and 4, a brief discussion is in order. Thus, four nasality-related processes will be introduced: retronusalization, denasalization, nasal spreading, and prenasalization.

2.4.2.1 *retronusalization*

Prenasalized stops nasalize the preceding vowel, as can be observed root-internally (11a), across morpheme boundaries (11b), and across glottal stops (11c). The process has been first observed proposed by F&H. In the examples to follow, the first line will give the orthography of the component morphemes along with their underlying phonological form; the second line—the practical orthography which variably reflects or does not reflect the phonological process under discussion along with the surface form of the word.

- (11) a. *sumbu* /so^mbo/ b. *ji-ngi* /hi^ŋgi/ c. *i-’ngi* /i?^ŋgi/
- sumbu* [sõ^mbo] *jingi* [hi^ŋgi] *i’ngi* [i?^ŋgi]
- ‘come out’ ‘come-1’ ‘bring-ven’

This process will be referred to as retronusalization. In the rule formulations to follow, T will stand for a plain stop, ^ND—a prenasalized stop, N—a nasal consonant, V—a vowel, and \tilde{V} —a nasal vowel.

RETRONASALIZATION

V → \tilde{V} / _ (?) ^ND

A prenasalized stop nasalizes the preceding vowel (across a glottal stop).

Nasality of vowels left-adjacent to prenasalized stops is not separately reflected in the orthography. This convenient convention means that the *ns* and *ms* accompanying prenasalized stops play a double role: they represent the prenasalization of the stop and the nasality of the preceding vowel.

2.4.2.2 denasalization

Word-initially, the prenasalization of glottal stops has shorted duration and lower intensity (12), the phonetics of which are reported by Repetti-Ludlow et al. (2019).

- (12) a. *bûthu* /^mbit^ho/ b. *da* /ⁿda/ c. *geñu* /^ŋgẽnõ/
- bûthu* [^mbit^ho] *da* [ⁿda] *geñu* [^ŋgẽnõ]
- ‘run’ ‘become’ ‘plantain’

This process will be referred to as denasalization.

DENASALIZATION

^ND → \tilde{N} D / # _

Preasalization is weakened word-initially.

Denasalization is reflected in the orthography, with *b* [^mb], *d* [ⁿd], *z* [ⁿdz], *dy* [ⁿdʒ], and *g* [^ŋg] spelled without *ms* and *ns*.

2.4.2.3 nasal spreading

The prominence of nasalization in the language is greatly magnified by robust progressive nasalization, whereby nasality of one segment “trickles down” further segments and across syllable boundaries (F&H). Nasal segments can be observed to spread their nasality onto following vowels (13a-c) and sonorant consonants (13a-b), even across glottal consonants (13c).

- (13) a. *na=ve* /nave/ b. *jin-ye* /j̩ye/ c. *an-’je* /ã?he/
name [nãmẽ] *jiñe* [j̩ñe] *an’jen* [ã?hẽ]
‘fruit-ABS’ ‘be-INF’ ‘eat-IMPV’

This process will be referred to as nasal spreading.

NASAL SPREADING, iterative
 $[+sonorant] \longrightarrow [+nasal] / [+nasal] [+glottal]_o -$
A sonorant nasalizes after a nasal phoneme (across glottals); applies iteratively.

Nasal spreading is partially reflected in the orthography. Segments nasalized in the course of nasal spreading are spelled as such, except vowels adjacent to nasal consonants.

2.4.2.4 *prenasalization*

Lastly, plain stops can often be observed to turn into prenasalized stops after nasal vowels. It is evident in patterns of borrowings from Spanish (14a) as well as a number of functional morphemes, which have nasal allomorphs after nasal vowels (14b). Oral and nasal allomorphs for suffixes of interest will be given in Sections 4.5.2 and 4.5.3.

- (14) a. *compadre* /kompaðre/ b. *an-’ta* /ã?ta/
kumba [kõ^mba] *a’nda* [ã?ⁿda]
‘godfather’ ‘eat-NEW’

This process will be referred to as prenasalization.

PRENASALIZATION, non-general
 $T \longrightarrow ^N D / \tilde{V}(?) -$
A plain stop prenasalizes after a nasal vowel (across a glottal stop).

Prenasalization is reflected in the orthography, with Spanish borrowings and nasal allomorphs spelled with prenasalized stops.

Prenasalization is not an exceptionless. Other Spanish borrowings (15a) as well as the preponderance of $\tilde{V}C\tilde{V}$ forms in the language (15b) suggest that nasal spreading can apply across plain obstruents as well.

- (15) a. *cotón* /koton/ b. *sinsin* /sĩsi/
kuntun [kõtõ] *sinsin* [sĩsĩ]
‘shirt’ ‘louse’

For a detailed investigation of nasality-related processes in the language and a diachronic discussion of nasal spreading and prenasalization, see AnderBois and Sanker (2019).

2.4.3 diphthongal mutations

In addition to nasalization, other processes relevant to the data of Chapter 3 and 4 include changes of vowel quality in diphthongs. These processes will be referred to as diphthongal mutations. The two processes to be discussed in this section are diphthongal ikavism and diphthongal rounding.

2.4.3.1 diphthongal ikavism

The vowels *e* /e/ and *û* /î/ undergo raising and fronting when adjacent to *a* /a/ in order to create well-formed diphthongs (see Section 2.4.1). This is most easily demonstrated with the causative CAUS suffix, which has three phonologically conditioned allomorphs: *-ñā* /nã/, *-en* /ě/, and *-an* /ã/. The first one surfaces on monosyllables (16a). The second one surfaces on *a*- and *u*-final words (16b-c). The third one surfaces on *e*-, *i*-, and *û*-final words (16d-f).

|------|---|---|--|
| (16) | a. <i>khûi-ñā</i> /k ^h ĩjñā/ | b. <i>i'na-en</i> /i? ^h nāe/ | c. <i>fiyu-en</i> /fijõe/ |
| | <i>khûiñā</i> [k ^h ĩjñā] | <i>i'naen</i> [i? ^h nāi] | <i>fiyuen</i> [fijõe] |
| | 'lie-CAUS' | 'cry-CAUS' | 'curl up-CAUS' |
| | "put" | "make cry" | "curl up" |
| | d. <i>dûse-an</i> /d ^h seā/ | e. <i>pûvi-an</i> /p ^h vīā/ | f. <i>a'jû-an</i> /a? ^h fā/ |
| | <i>dûsian</i> [d ^h siā] | <i>pûvian</i> [p ^h vīā] | <i>a'jian</i> [a? ^h iā] |
| | 'hang-CAUS' | 'turn-CAUS' | 'vomit-CAUS' |
| | "hang" | "turn" | "make vomit" |

Of the six cases above, three involve underlying vowel sequences which do not constitute legal diphthongs: *aen* /æe/ (16b), *ean* /ěa/ (16d), and *uan* /ã/ (16f). These are resolved to [ai], [iã], and [iã], respectively. This process will be referred to as diphthongal ikavism.¹

Diphthongal ikavism
[-low, -round] → i / { _ a, a _ }
e and *î* become *i* when adjacent to *a*.

Although demonstrated with causative forms above, diphthongal ikavism is a generally productive rule (17).

¹ By analogy with Ukrainian, where *ikavism* refers to the phonologically-conditioned shift of Proto-Slavic *e and *o to modern-day i (Carlton, 1974).

- (17) a. *ze'nze-a* /^ňdzē?ⁿdza/ b. *inzû-a* /ⁱn^ňdžia/
- ze'nzia* [^ňdzē?ⁿdžia] *inzia* [ⁱn^ňdžia]
- 'painted-ADN' 'green-ADN'

Diphthongal ikavism is partially reflected in orthography: while /æ/ [ã] is spelled *aen*, reflecting its underlying form, /eã/[iã] and /fã/[iã] are both spelled *ian*, reflecting their surface forms.

Diphthongal ikavism provides further support for considering *ia* /ia/ a diphthong (see [Section 2.4.1](#)): otherwise the process could not be motivated as a rule ensuring output well-formedness.

2.4.3.2 *diphthongal rounding*

The vowel *a* /a/ becomes rounded when in sequences of *ae* /ae/ and *ai* /ai/ and preceded by a labial consonant. The rule applies within one stem ([18a-b](#)), across morpheme boundaries ([18c-d](#)), in native roots ([18a](#)), and in borrowings ([18b](#)).

- (18) a. *fae* /fae/ b. *bailar* /bailar/
- fae* [foe] *buira* [^ňboira]
- 'one' 'dance'
- c. *sema-en* /semãe/ d. *atapa-en* /atapãe/
- semuen* [semõe] *atapaen* [atapoẽ]
- 'work-CAUS' 'breed-CAUS'
- "make work" "breed"

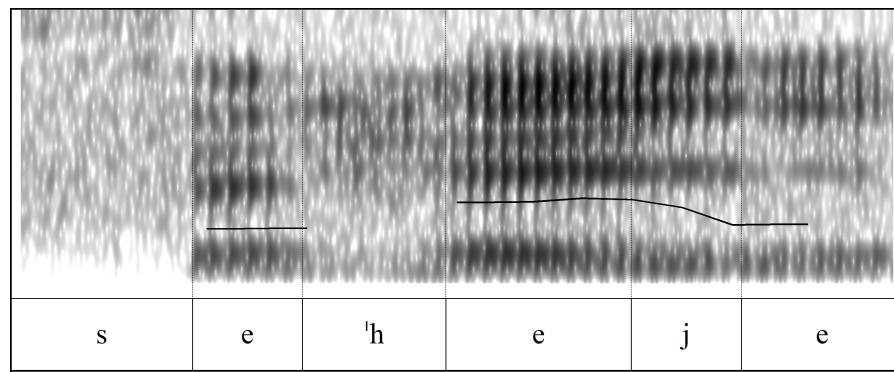

This process will be referred to as diphthongal rounding. It has not been observed in previous literature.

DIPHTHONGAL ROUNDING
 a → o / [+labial] _ [-back]
ae and ai become oe and oi, respectively, after labial consonants.

An additional piece of evidence in favor of the rule comes from the absence of lexical forms in which /ae/ follows a labial consonant—despite the presence of the orthographic *ae*, here understood as reflecting the underlying /æ/. On the whole, diphthongal rounding is inconsistently reflected in the orthography. Even morphologically complex forms can be spelled in a way reflecting their surface ([18c](#)) or the underlying form ([18d](#)) forms.

2.5 PHONETICS OF STRESS AND GLOTTAL STOPS

Stress in A'ingae correlates most robustly with duration and pitch (19). The y-axis represents duration. The black line drawn over the spectrogram represents pitch.

- (19) *sejé-ye*
 'cure-PASS'

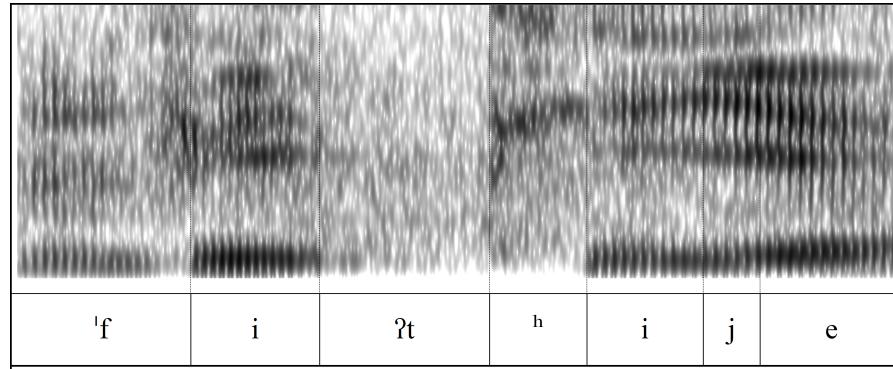

The correlation between duration and stress can be partially beclouded by phrase-level effects: although the stressed syllable is commonly the longest in a stress group, the final syllable can be characterized by phonetic elongation, too, as well as a lowering of pitch (M. B. Borman, 1962; Repetti-Ludlow et al., 2019). This does not impede correct identification of the stressed syllable, as stress is almost never ultimate.

There are bidirectional phonological and phonetic interactions between glottal stops. As the realization of glottal stops depends on the placement of stress and the placement of stress depends on the presence of glottal stops. The phonological conditioning of stress by glottal stops will be discussed in detail in [Section 4.5](#).

The realization of glottal stops ranges from full glottal closure to creaky voice, to complete deletion. The variation between full glottal closure and creaky voice is taken to be a matter of phonetic detail. It will be discussed here only briefly, as it is largely outside of the scope of this study. The complete deletion of glottal stop is given a phonological interpretation. It will be analyzed in [Section 4.5.2](#).

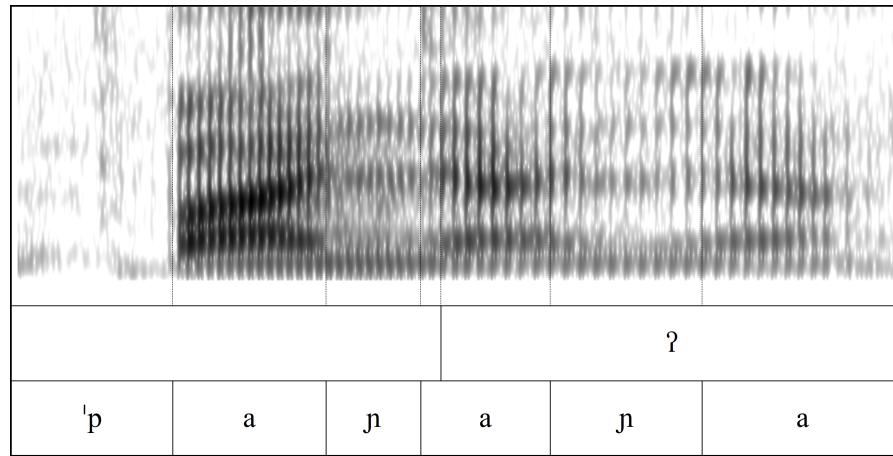

M. B. Borman (1962) observes that the glottal stop is "fortis when closing a stressed syllable, and lenis, varying to actualization as laryngealization, when closing an unstressed syllable" (p. 51). This is corroborated in so far as the glottal stop can be realized as glottal closure in tonic (i.e. stressed) syllables (20) and with creaky voice in posttonic (i.e. immediately following the tonic) syllables (21).

In (20), the glottal stop is realized as a glottal closure and followed by an aspirated alveolar stop /? t^h /, which can be seen on the spectrogram as a long pause.

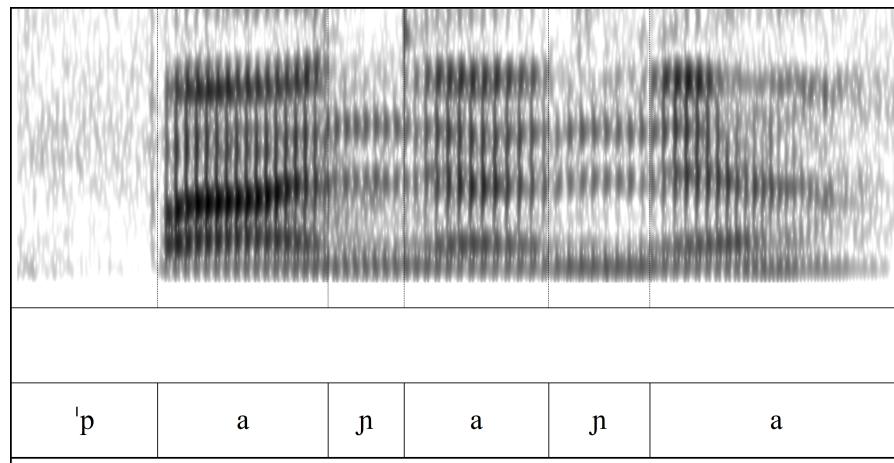

- (20) *f'i'thi-ye*
'kill-INF'

In (21), the glottal stop is realized as creak, which is reflected in the spectrogram as the striations start broadening where a glottal stop is expected. For a non-creaky realization, compare (21) to the minimally different (22), where striations near the right word boundary are much narrower.

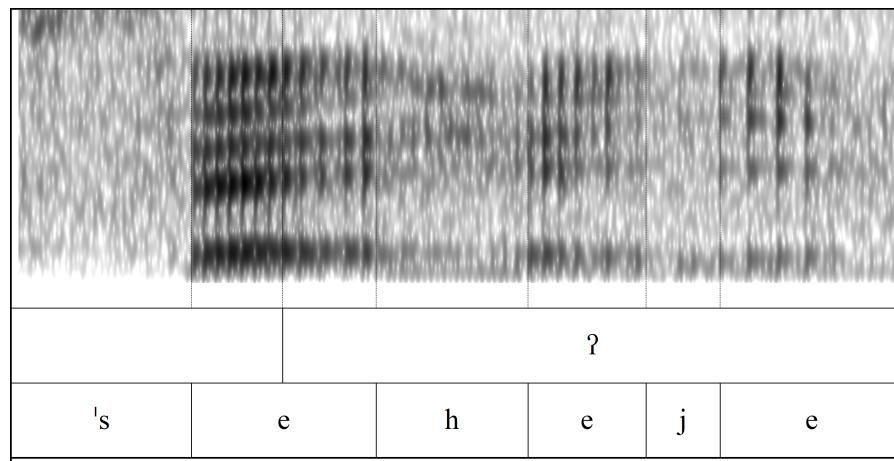

- (21) *páña-'ñá*
'hear-VER'

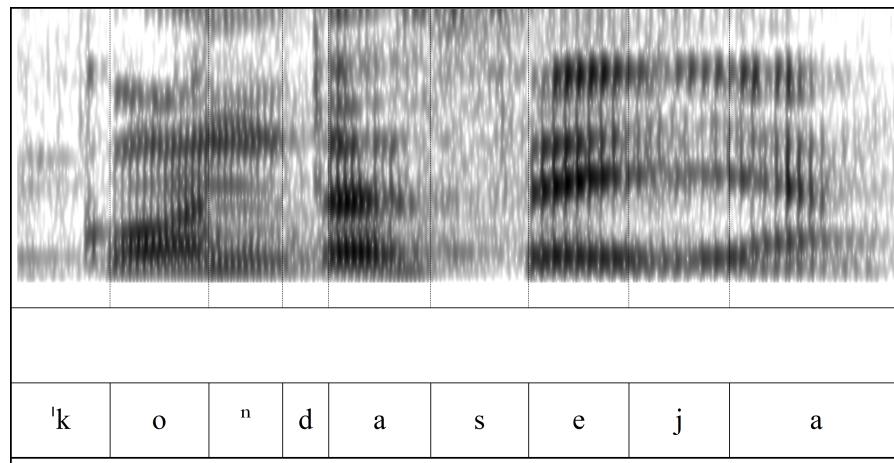

- (22) *páña-ña*
'hear-IRR'

M. B. Borman (1962)'s picture, however, is not exhaustive, as glottal stops can be realized with creaky voice on tonic syllables as well (23). The creaky realization is not restricted to the glottalized syllable and once begun it can extend across the rest of the word (21, 23).

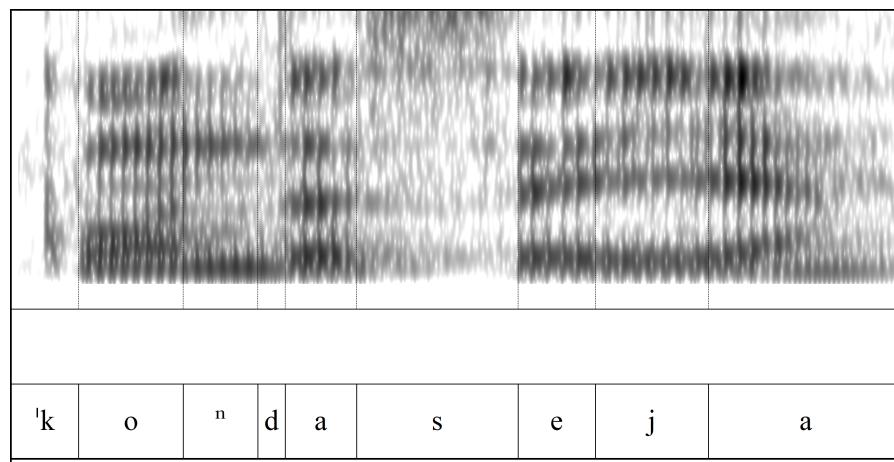

- (23) *sé'je-ye*
'cure-INF'

Lastly, the realization of glottal stops in syllables other than the tonic and the posttonic is much weaker, up to the point of deletion. There is no significant noticeable difference in the breadth of striations anywhere between (24) and (25), although the two have different morphological composition. Glottal stop deletion will be understood as a phonological process, which will be given an account in Sections 4.5.2 and 4.5.3.

- (24) *kúndase-'*
 'tell-VER'

- (25) *kúndase-ya*
 'tell-IRR'

3

VERBAL MORPHOLOGY

Verbal morphology is the richest in the language and interacts with stress in complex, interesting ways. The conjunction of these two facts invited the present study.

Section 3.1 presents and describes the inflectional template of the A'ingae verb. Section 3.2 motivates its deviations from F&H's proposal. Finally, Section 3.3 considers the question of the syntactic status of A'ingae verbal morphemes.

3.1 INFLECTIONAL TEMPLATE

Almost all functional morphemes of the language can be found at the right edges of words. Suffixes and enclitics abound; prefixes and proclitics are virtually absent.¹

The inflectional template of the A'ingae verb encodes multiple semantic and pragmatic categories in a dozen or so slots. Voice-related slots host suffixes that change the valence of the root to which they attach. They are followed by slots for aspect ASP, associated motion MOT, subject number NUM, modality MOD, polarity POL, taxis TAX, topic TOP, focus FOC, illocution ILL, and subject person PER suffixes. All the slots along with the suffixes which inhabit them are given in the morphological template. More detail on the verbal inflections will be momentarily given.

The morphological template on the next page captures the ordering of inflectional morphemes as well as the co-occurrence restrictions that obtain among them. As such, it is a visual representation of a generative algorithm for A'ingae conjugation. To generate a legal verbal form, go from left to right picking at most one morpheme per column along the way. Do not cross the horizontal lines.

¹ In some dialects, a glottal stop can be infixated to express pluractionality. Reduplication of a part of the stem expresses similar semantics (F&H).

F&H identify morphological vowel lengthening and analyze it as the durative aspect. Sanker, Silva, Lucitante, and AnderBois (2018) identify falsetto and analyze it as a shift in narrative perspective. The lengthening identified by F&H and the falsetto identified by Sanker et al. (2018) might or might not be the same phenomenon.

Although glottal stop infixation, stem reduplication, and vowel lengthening *alias* falsetto all three have prosodic correlates, they are beyond the scope of this study.

VOICE / VALENCE	ASP	MOT	NUM	MOD	POL	TAX	TOP	FOC	ILL	PER

	IMP	IMP2	IMP3	PRHB						

Morphological template of verbal inflection, 1st iteration.

The rest of this section is a brief description of the various morphological slots and suffixes, given here mainly for purposes of documentation. A reader interested strictly in the questions of morphophonology should feel free to skip it.

The three leftmost slots in the inflectional template for the inflection correspond to the three valence-changing suffixes: the causative voice *-ña* 'CAUS,' whose allomorphs *-en* and *-an* are discussed in [Section 2.4.3.1](#), the reciprocal voice *-khu* 'RCPR,' and the passive voice *-ye* 'PASS', whose nasal allomorph is *-ñe*. The three suffixes can co-occur on one verb in the order of introduction

The voice suffixes are followed by the aspectual ASP suffixes, which include the imperfective *-je* 'IMPV' (nasal allomorph *-jen*), the pre-cumulative *-ji* 'PRCM' (nasal allomorph *-jin*, the semelfactive *-ñakha* 'SMFC', and the verbal diminutive *-kha* 'DMN.'

The associated motion MOT suffixes include the venitive *-ngi* 'VEN' and the andative *-nga* 'AND.' The aspectual and associated motion suffixes are mostly incompatible, with the exception of the imperfective *-je* 'IMPV,' which can co-occur with either associated motion suffix.

The only subject number NUM suffix is the plural subject *-fa* 'PLS.' As indicated by the gloss, it expresses the plurality of subject, not action (F&H). Pluractionality is expressed by glottal stops insertion or reduplication of a part of the stem, which processes are beyond the scope of the current study.

The plural subject suffix can be followed by the irrealis *-ya* 'IRR' (nasal allomorph: *-ña*), which is the only morpheme in the slot designated for modal MOD suffixes. While the irrealis is not the only morphologically encoded modal category in the language, others are mixed in with the taxis suffixes, two morphological slots down the road.

Between the modal and the taxis suffixes, there is the negative *-mbi* 'NEG,' which is the sole polarity POL suffix.

The taxis TAX suffixes comprise a large number of heterogeneous morphemes with few semantic commonalities. The category should rather be conceived of syntactically, as taxis suffixes play an important (though not unique) role in determining the (in)dependent status of a clause.

Among suffixes associated chiefly with dependent clausal status, we find the infinitival *-ye* 'INF,' as well as the hypotactic HYP suffixes: the same subject *-pa* 'ss,' the different subject *-si* 'ds,' the frustrative *-ma* 'FRST,' the locative *-ni* 'loc,' and the apprehensional *-sa'ne* 'APPR.'

The infinitival *-ye* 'INF' (nasal allomorph: *-ñe*) can create argument clauses or adjunct clauses with purpose-like semantics. The same sub-

ject *-pa* 'ss' (nasal allomorph: *-mba*) and the different subject *-si* 'ds' index subject coreference between two clauses.² The frustrative *-'ma* 'FRST' marks an unfulfilled expectation. The locative *-ni* 'loc' relates two clauses temporarily. The apprehensional *-sa'ne* 'APPR' encodes a potential undesirable situation (for more details, see Dąbkowski and AnderBois, *forthcoming*).

The hypotactic suffixes are listed below the inflectional and referenced as HYP in the taxis TAX column. Their presentation outside the main template is primarily due to the high number of taxis suffixes, although there is also a real difference between the infinitive and other hypotactic suffixes: the infinitive does not independently express modality or polarity (i.e. does not combine with either of *-ya* 'IRR' or *-mbi* 'NEG'), whereas the suffixes referred to as hypotactic do.

Among suffixes associated chiefly with independent clauses status, we find the veridical *-ya* 'VER' (nasal allomorph: *-ñña*) of rather elusive semantics (for more, see the discussion of the assertive clitic in F&H), as well as the directive suffixes: the three imperatives *-ja* 'IMP' (nasal allomorph: *-jan*), *-kha* 'IMP2,' *-se* 'IMP3,' and the prohibitive *-jama* 'PRHB.' The semantic differences between the three imperative morphemes are not well understood. The *-jama* 'PRHB' expresses prohibitions.

The directive suffixes are listed beneath the inflectional template and referenced as DCV in the taxis TAX column. Here again, the visual displacement of the directive suffixes is primarily for reasons of visual compactness, although there is obviously a clear split between the veridical and the directive suffixes in their illocutionary force.

The topic TOP and focus FOC suffixes include the new topic *-ta* 'NEW', the contrastive topic *-ja* 'CNTR' and the additive focus *-khe* 'ADD.' The topic suffix relate clauses in conditional fashion. The differences between *-ta* 'NEW' (nasal allomorph: *-nda*) and *-ja* 'CNTR' (nasal allomorph: *-jan*) are not well understood. The semantics of the additive focus *-khe* 'ADD' is roughly equivalent to the English additive particle *too*.

The illocutionary ILL suffixes comprise the reportative *-te* 'RPRT' (nasal allomorph: *-nde*) and the polar interrogative *-ti* 'INT' (nasal allomorph: *-ndi*). If not followed by person suffix, they both entail a third person subject in the main clause.

² Among hypotactic clauses, Fischer (2007) further distinguishes between subordinate and co-subordinate clauses, and argues that the A'ingae *-pa* 'ss' and *-si* 'ds' can function in either dependency relation. While this is largely peripheral to morphophonology, some language-internal variation has been observed with respect to the accentual variation of *-pa* 'ss.' The potential interaction between the syntax and the phonology of *-pa* 'ss' are to be explored in further research.

The person PER suffixes include the first person *-ngi* '1', the second person *-ki* '2,' and the third person *-tsû* '3.' They encode, often redundantly, the subject of the main clause. The directive suffixes can be followed by the composite *-teki* 'RPRT.2', which expresses a reported imperative or a reported prohibition.

3.2 EMPIRICAL REFINEMENTS

The only attempt to date at constructing a comprehensive morphological template of the A'ingae verb has been made by F&H, who refer to it as the "template of the predicate phrase" (p. 30). The template proposed here differs from that of F&H in several ways: it includes some functional morphemes which F&H do not include, excludes others, and thoroughly reorganizes the way they are categorized, making different prediction on their ordering and co-occurrence. Some of the major deviations from F&H's template will be discussed and motivated in this section.³

The template I am proposing is restricted to inflectional morphemes, where inflectional morphemes are understood as those which preserve the morphosyntactic category of verbhood. Although derivational morphemes also interact with stress in unpredictable ways, they are largely outside of the scope of this study (but see [Section 4.5.2](#), where the nominalizing subordinator *-chu* 'SBRD' is discussed due to its unique accentual properties, unencountered among inflectional morphemes).

Generally, the template I am proposing is richer than F&H's due to the inclusion of many morphemes recognized in both works, but excluded from the verbal template by F&H. Among the morphemes discussed by F&H, but not included in the template, we find the early-attaching valence suffixes, and some of the later-attaching one: the hypotactic, topic, focus, illocution, and person morphemes.⁴ A study of many of these morphemes will be central to understanding the interactions between morphology and prosody of A'ingae.

³ Aside from their organization in a template, the very form of many morphemes assumed here differs from the forms proposed by F&H. Some of the preglottalized morphemes, e.g. the semelfactive *-nakha* 'SMFC,' the venitive *-ngi* 'VEN,' the andative *-nga* 'AND,' or the apprehensional *-sa'ne* 'APPR,' are transcribed by F&H without glottal stops (although see M. B. Borman, [1976](#) for a transcription of these morphemes with glottal stops, corroborating my analysis). A possible explanation for these differences is discussed briefly in a footnote on page [73](#).

⁴ Valence suffixes were excluded by F&H from the template of the predicate phrase presumably on the grounds of their derivational status. The later-attaching morphemes were excluded from the template of the predicate phrase presumably on the grounds of their association with the entire clause, not the predicate.

In addition to the above inclusions, the structure of the template has been reorganized. The reorganization results in different predictions on the ordering and co-occurrence of functional morphemes. Three major changes are motivated in what follows.

First, I group the negative *-mbi* 'NEG' and the frustrative *'ma* 'FRST' in two consecutive morphological slots, predicting their co-occurrence. I group the frustrative *'ma* 'FRST' and the veridical *'ya* 'VER' in one morphological slot, predicting their mutual exclusivity.

F&H group the negative *-mbi* 'NEG' and the frustrative *'ma* 'FRST' in one morphological slot, arguably predicting their mutual exclusivity. They locate the veridical *'ya* 'VER' in a morphological slot following *'ma* 'FRST,' arguably predicting their co-occurrence.

The negative *-mbi* 'NEG' and the frustrative *'ma* 'FRST' have been attested to co-occur (26a). The frustrative *'ma* 'FRST' and the veridical *'ya* 'VER' cannot co-occur (26b).

- (26) a. *indi-mbi-'ma* (Quenamá, 1992, p. 25)
 'catch-NEG-FRST'
 b. **panza-'ma -'ya*
 'hunt-FRST-VERB'

Second, I locate the infinitival *-ye* 'INF' in a slot following the plural subject *'fa* 'PLS,' predicting that *-ye* 'INF' attaches after *'fa* 'PLS.' I prohibit the co-occurrence of the infinitival *-ye* 'INF' with the negative *-mbi* 'NEG,' the unrealis *-ya* 'IRR,' or the directive suffixes.

F&H locate the infinitival *-ye* 'INF' in a morphological slot followed by the plural subject *'fa* 'PLS,' the negative *-mbi* 'NEG,' the unrealis *-ya* 'IRR,' and the directive suffixes, arguably predicting their co-occurrence in that order.

The plural subject *'fa* 'PLS' comes before *-ye* 'INF' (27a). The infinitival *-ye* 'INF' does not combine with the negative *-mbi* 'NEG' (27b), the unrealis *-ya* 'IRR' (27c), or directive suffixes (27d-e) in either order.

- (27) a. *avúja-'fa-ye* (Blaser and Umenda, 2008, p. 7)
 'rejoice-PLS-INF'
 b. *panza(*-ye)-mbi(*-ye)* c. *panza(*-ye)-ya(*-ye)*
 'hunt(-INF)-NEG(-INF)' 'hunt(-INF)-IRR(-INF)'
 d. *hunt(*-ye)-ja(*-ye)* e. *panza(*-ye)-jama(*-ye)*
 'hunt(-INF)-IMP(-INF)' 'hunt(-INF)-PRHB(-INF)'

Third, I propose one morphological slot for the aspect suffixes: the imperfective *-je* 'IMPV,' the precumulative *-ji* 'PRCM,' the semelfactive *-ñakha* 'SMFC,' and the verbal diminutive *-'kha* 'DMN'. I propose

another morphological slot for the associated motion suffixes: the venitive *-'ngi* 'VEN' and the andative *-'nga* 'AND'. I permit only one aspectual morpheme, the imperfective *-je* 'IMPV' to combine with the associated motion suffixes.

F&H put aspectual and associated motion suffixes in one morphological slot, arguably predicting their mutual exclusivity.⁵

The precumulative *-ji* 'PRCM,' the semelfactive *-ñakha* 'SMFC,' and the verbal diminutive *-kha* 'DMN' are incompatible with the associated motion suffixes (28a-c). The imperfective *-je* 'IMPV' is compatible with both the venitive *-'ngi* 'VEN' and the andative *-'nga* 'AND' (28d).

- | | | | |
|-----------|--------------------------------|----------------------------------|----------------------------------|
| (28) a. * | <i>panza-ji{-'ngi, -'nga}</i> | b. * | <i>panza-ñakha{-'ngi, -'nga}</i> |
| | 'hunt-PRCM{-VEN, -AND}' | | 'hunt-SMFC{-VEN, -AND}' |
| c. * | <i>panza-kha{-'ngi, -'nga}</i> | d. <i>panza-je{-'ngi, -'nga}</i> | |
| | 'hunt-DMN{-VEN, -AND}' | | 'hunt-IMPV{-VEN, -AND}' |

Finally, on top of including some functional morphemes and reorganizing others, the template I propose eliminates three suffixes: the adjectivizer *-tshi* 'ADJ,'⁶ the prospective *-yi* 'PRSP,' and the movement manner *-in* 'MVM.' In what follows, I will briefly outline reasons for these exclusions.

The adjectivizer *-tshi* 'ADJ' is glossed by F&H as the "quality marker" and included among aspectual suffixes. There three reasons for not considering it an aspectual suffix.

First, unlike other aspectual morphemes (the imperfective *-je* 'IMPV,' the precumulative *-ji* 'PRCM,' the semelfactive *-ñakha* 'SMFC,' and the verbal diminutive *-kha* 'DMN'), the adjectivizer *-tshi* 'ADJ' does not combine with valence suffixes. It attaches to bare stems only.

Second, the adjectivizer *-tshi* 'ADJ' is not productive. New forms cannot be freely constructed, and the existing ones often display semantic idiosyncrasies (29-30a) or cannot be related to any independently existing verb (29-30b).

⁵ To be precise, F&H predict the co-occurrence of the imperfective *-je* 'IMPV' and the andative *-'nga* 'AND' by associating what I dub the andative with two different morphological slots. The morpheme incompatible with *-je* 'IMPV' is labeled as "translocative." The morpheme compatible with the imperfective is labeled as "distal" (p. 30). The proposal advanced here avoids this redundancy.

⁶ The adjectivizer often appears without the glottal stop as well: *-tshi* 'ADJ.' Due to the low productivity of the suffix, it is difficult to tell which form is the underlying one.

- (29) a. *in'jan*
 'want'
 b. **chhara*
 int.: "shine"
- (30) a. *injan'tshi*
 'many'
 b. *chhara'tshi*
 'bright'

Third, forms with *-tshi* 'ADJ' are of a different syntactic category than verbs. Although they can function predicatively (31a), like verbs (31b), they can also combine with the adnominal marker *-a* 'ADN' to modify nouns directly (32a), while verbs cannot (32b).⁷

- (31) a. *dû'shû=tsû avûja-tshi*
 'child=3 rejoice-ADJ'
 '"a child is happy"'
 b. *dû'shû=tsû avûja*
 'child=3 rejoice'
 '"a child is happy"'
- (32) a. *avûja-tshi-a dû'shû*
 'rejoice-ADJ-ADN child'
 '"a happy child"'
 b. **avûja-a dû'shû*
 'rejoice-ADN child'
 'int.: "a happy child"'

Thus, *-tshi* 'ADJ' is better understood as a derivational morpheme. Due to its the adjective-like semantics, I gloss it as an *adjectivizer*. The same observation led F&H to glossing it as the "quality marker."

The movement manner *-in* 'MVM' is analyzed by F&H as a marker of "simultaneity" and included among relative tense morphemes. It is, however, attested exclusively as an argument of verbs of motion where it expresses the manner of motion (33). The movement manner *-in* 'MVM' attaches to bare stems only and does not permit the attachment of any further suffixes.

- (33) a. *kha'ya-in ja* (Chica Umenda and R. Borman, 1982, p. 12)
 'swim-MVM go'
 '"swim away"'
 b. *bûthu-in ji* (Blaser and Umenda, 2008, p. 24)
 'run-MVM come'
 '"come running"'

A'ingae is thus revealed to be a verb-framed language with a suffix devoted specifically to expressing the manner of motion.

The purpose of motion is expressed with the attributive *-su* 'ATTR' (34). Although the attributive *-su* 'ATTR' is highly polysemous, as a purpose of motion marker its distribution is like that of *-in* 'MVM.'

⁷ The third person subject morpheme coheres phonologically with verbs, but not with nouns. It is therefore glossed variably as a suffix *-tsû* '3' or a clitic *=tsû* '3'. For a discussion of affixal and enclitic properties, see Section 3.3.

- (34) a. *simba-’sû ja* (Blaser and Umenda, 2008, p. 204)
 ‘fish-ATTR go’
 “go fishing”
- b. *pasia-’sû ji* (R. Borman, 1965, p. 18)
 ‘ride-ATTR come’
 “come for a ride”

Lastly, the prospective *-yi* ‘PRSP’ is included by F&H among the aspectual suffixes. It is, as F&H themselves observe, attested only with one verb, *ja* ‘go’ (35), which I take to be sufficient grounds for not considering it a proper aspectual morpheme.

- (35) a. *ja* b. *jayi*
 ‘go’ ‘go.PRSP’
 “go” “be going”

Although the prospective *-yi* ‘PRSP’ is found only on *ja* ‘go,’ it has its counterpart *-ña* ‘PRSP,’ which, in turn, is found only on *ji* ‘come’ (36). I treat these two as irregular prospective forms of motion verbs.

- (36) a. *ji* b. *jiña*
 ‘come’ ‘come.PRSP’
 “come” “be coming”

3.3 CLITICHOOD

The last major deviation of my analysis from F&H’s is the syntactic status of the A’ingae verbal morphology. While I have referred to all of the verbal morphemes discussed so far as suffixes, F&H take most of them to be clitics. In this section, I will motivate my departure from F&H’s analysis.

Suffixes are bound morphemes which attach to syntactically independent words. Clitics are morphemes which syntactic characteristics of an independent word, but are phonologically dependent on another independent word or phrase.

F&H assign the clitic status to great many morphemes, across many different syntactic and functional categories. In arguing for their clitichood, they invoke their ability to attach to words of different syntactic categories (p. 11). Among many others, F&H analyze as clitics the human plural morpheme *=ndekhû* ‘HPL,’ the adverbializer *=e* ‘ADV,’ and the honorific *=ye* ‘HONR.’⁸

⁸ The equals sign = is used throughout this paragraph to reflect F&H’s analysis.

Importantly, they assign the clitic status to all the verbal morphemes other than the valence, aspect, and associated motion suffixes.⁹ This includes the plural subject =’fa ‘TLS,’ the unrealis =ya ‘IRR,’ the negative =mbi ‘NEG,’ the imperative =ja ‘IMP,’ the prohibitive =jama ‘PRHB,’ the interrogative =ti ‘INT,’ the reportative =te ‘RPRT,’ the subject person =ngi ‘1,’ =ki ‘2,’ and =tsû ‘3,’ and others.⁸

Finally, they assign the clitic status to all the case markers, including the accusative =ma ‘ACC,’ the absentive =ve ‘ABS,’ the dative =nga ‘DAT,’ the benefactive =mbe ‘BEN,’ the locative =ni ‘LOC,’ the ablative =ne ‘ABL,’ and others.

I propose that most of the verbal morphemes, up to the illocution ILL and person PER slots, should be analyzed as suffixes, not clitics. The illocution and person morphemes straddle the line: they are clitics, but with some suffixal properties.

The table below abstracts away from the morphological template information about individual morphemes and shows only their affixal or enclitic status, as proposed by F&H and here. The hyphen – is used for affixes. The equals sign = is used for clitics. The approximately equals sign ≈ is used for ambiguous clitics with some affixal properties. As they have phonological properties of suffixes when attached to verbs (which is central to the questions of verbal morphophonology), they have been glossed with hyphens in the inflectional template and will be glossed as such in [Chapter 4](#).

	VOI	ASP	MOT	NUM	MOD	POL	TAX	TOP	FOC	ILL	PER
F&H	–	–	–	=	=	=	=	=	=	=	=
HERE	–	–	–	–	–	–	–	–	–	≈	≈

Morphological template of verbal inflection, schematized.

Although my analysis deviates from F&H’s in treating most verbal morphemes as suffixes, it is continuous with it in treating case markers as clitics. Thus, while non-verbal morphology is not the central focus of my work, it will be instructive to contrast verbal morphemes with the case markers. To motivate my partial departure from F&H’s analysis, I will demonstrate that most of the verbal morphemes differ from the case markers in their syntactic status. To show the different status of verbal morphemes and case markers, I invoke the first three

⁹ The distinction F&H make between clitics and suffixes maps roughly onto a distinction between level 0 and level 1 inflectional suffixes I will make in [Section 4.3](#). I assign valence suffixes, associated motion suffixes, and a majority of the aspectual suffixes to level 0, and all other verbal morphemes to level 1. Thus, the distinction F&H made between suffixes and clitics has a real correlate in the morphophonology of A’ingae. Nevertheless, it is neither necessary nor sufficient to account for it, and as will be shown in this section, there are reasons not to adopt it.

of the six criteria for distinguishing suffixes from clitics proposed by (Zwicky and Pullum, 1983, henceforth Z&P, p. 503–504).

The data I will present now is representative of the number NUM, modality MOD, polarity POL, taxis TAX, topic TOP, and focus FOC morphemes, where my analysis is divergent from that of F&H. Subsequently, I will consider how the illocution ILL and person PER morphemes fair against Z&P's criteria.

The first of Z&P's criteria pertains to freedom of host selection.

CRITERION A

Clitics can exhibit a low degree of selection with respect to their hosts, while affixes exhibit a high degree of selection with respect to their stems.

The word order in A'ingae matrix clauses is free. The nominal and verbal dependents can come either before or after the head. This allows us to observe that while case markers attach at the level of the phrase (37), verbal morphemes attach at the level of the head (38–39). Brackets are used to indicate the constituent to which the functional morpheme attaches.

- | | | |
|------|---|---------------------------------------|
| (37) | a. [rande kini'khu]=ma | b. [kini'khu rande]=ma |
| | '[large tree]=ACC' | '[tree large]=ACC' |
| | "a large tree.ACC" | "a large tree.ACC" |
| (38) | a. <i>kini'khu=ma</i> [<i>thûthû</i>]-'fa | b. *[<i>thûthû kini'khu=ma</i>]-'fa |
| | 'tree=ACC [fell]–PLS' | '[fell tree=ACC]–PLS' |
| | "they felled a tree" | int.: "they felled a tree" |
| (39) | a. <i>ja'ñu</i> [<i>thûthû</i>]-'fa | b. *[<i>thûthû ja'ñu</i>]-'fa |
| | 'today [fell]–PLS' | '[fell today]–PLS' |
| | "they felled it today" | int.: "they felled it today" |

The case markers are associated with the noun phrase. They can attach to the head of the phrase (37a), but also to its modifier if it comes second (37b). Thus, case markers exhibit freedom of host selection. The same cannot be said of verbal morphemes, as they cannot attach an argument (38b) or a modifier (39b) of the predicate. Verbal morphemes do not exhibit a freedom of host selection.

The second of Z&P's criteria pertains to arbitrary gaps.

CRITERION B

Arbitrary gaps in the set of combinations are more characteristic of affixed words than of clitic groups.

There are arbitrary gaps found among the verbal morphemes. As was shown in [Section 3.1](#), the infinitival *-ye* 'INF' does not combine with

the negative *-mbi* ‘NEG’ (27b), the unrealis *-ya* ‘IRR’ (27c), or directive suffixes (27d-e). No arbitrary gaps have been observed with case markers.

The third criterion pertains to morphophonological idiosyncrasies.

CRITERION C

Morphophonological idiosyncrasies are more characteristic of affixed words than of clitic groups.

Before case markers and verbal morphemes are evaluated with respect to CRITERION C *sensu stricto*, observe that case markers do not form a part of the phonological word with their host, whereas verbal morphemes do. Thus, stress can shift when a verbal morpheme is attached to a verb (40-41b), but not when a case marker is attached to a noun (40-41a). This shows that there is a closer phonological association between the verb and the verbal morphemes—as is expected of affixes—than there is between the noun and the case markers—as is expected of clitics.

- | | |
|-------------------------|---------------------|
| (40) a. <i>khuvi</i> | b. <i>pánza</i> |
| ‘tapir’ | ‘hunt’ |
| (41) a. <i>khuvi=ma</i> | b. <i>panzá-mbi</i> |
| ‘tapir=ACC’ | ‘panza-NEG’ |

The close phonological association between the verb and the verbal morphemes allows for morphophonological idiosyncrasies, which are indeed attested. There is variation among verbal morphemes with respect to the stress they assign to one class of verbal roots (for an introduction to verbal classes, see Section 4.2). Thus, depending on the morpheme, the observed inflected form can have initial (42a) or stem-final (42b) stress. Case markers have not been observed to exhibit analogous morphophonological idiosyncrasies.

- | | |
|--------------------------|--------------------|
| (42) a. <i>áfa-sa'ne</i> | b. <i>afá-jama</i> |
| ‘speak-APPR’ | ‘speak-PRHB’ |

In an interim conclusion, the evaluation of case markers and verbal morphemes with respect to Z&P’s CRITERIA A, B, and C supports F&H’s analysis of case markers as clitics. The evaluation does not support F&H’s analysis of verbal morphemes as clitics—the verbal morphemes located in the slots for number NUM through focus FOC are instead demonstrated to be affixes.

Now I will consider the illocution ILL morphemes—the interrogative *≈ti* ‘INT’ and the reportative *≈te* ‘RPRT’—and the subject person PER morphemes—the first person *≈ngi* ‘1,’ the second person *≈ki* ‘2,’ and third person *≈tsû* ‘3.’

All the five morphemes surface in the second position in the clause (F&H; Dąbkowski and AnderBois, *forthcoming*). They Wackernagel clitics (Wackernagel, 1892). This is to say, they attach to the right edge of the first phase in a clause (43).

- | | |
|---|--|
| (43) a. <i>kanse\approxte tayupi</i> | b. <i>tayupi\approxte kanse</i> |
| ‘live \approx RPRT formerly’ | formerly \approx RPRT live |
| “used to live.RPRT” | “used to live.RPRT” |

As they are attested attaching verbs (43a), adverbs (43b), or nouns (31), they exhibit a complete freedom of host selection. Thus, they are clitics according to Z&P’s CRITERION A.

Evaluating the illocution and subject person morphemes against the other two of Z&P’s criteria complicates the picture.

There are arbitrary gaps found among the illocution and subject person morphemes. While the interrogative \approx *ti* ‘INT’ and the reportative \approx *te* ‘RPRT’ can co-occur with the first person \approx *ngi* ‘1,’ and second person \approx *ki* ‘2,’ subject morphemes (44a), they cannot co-occur with the third person subject morpheme (44b). Thus, they are affix-like according to Z&P’s CRITERION B.

- | | |
|---|---|
| (44) a. <i>panza{\approxte, \approxti}{\approxngi, \approxki}</i> | b. * <i>panza{\approxte, \approxti}\approxts\hat{u}</i> |
| ‘hunt{ \approx RPRT, \approx INT}{ \approx 1, \approx 2}’ | ‘hunt{ \approx RPRT, \approx INT} \approx 3’ |

The illocution and subject person morphemes cohere stress-wise with verbs, but not with other lexical classes. Thus, they can shift the stress of a verb (45-46a), but not, for example, an adverb (45-46b).

- | | |
|---|--|
| (45) a. <i>pánza</i> | b. <i>tayúpi</i> |
| ‘hunt’ | ‘formerly’ |
| (46) a. <i>panzá\approxki tayupi</i> | b. <i>tayúpi\approxki panza</i> |
| ‘hunt \approx 2 formerly’ | ‘formerly \approx 2 hunt’ |
| “you used to hunt” | “you used to hunt” |

Lastly, the illocution and subject person morphemes exhibit morphophonological idiosyncrasies with respect to nasalization. The interrogative \approx *ti* ‘INT’ and the reportative \approx *te* ‘RPRT’ have nasal allomorphs \approx *ndi* ‘INT’ and \approx *nde* ‘RPRT’ which surface after nasal vowels (47a). The forms of the person subject morphemes \approx *ngi* ‘1,’ \approx *ki* ‘2,’ and \approx *ts \hat{u}* ‘3’ are constant; they do not undergo prenasalization (47b). Thus, the illocution and subject person morphemes are affix-like according to Z&P’s CRITERION C.

- (47) a. **pañazti*
 pañazndi
 'hunt≈INT'
 b. *pañaztsû*
 **pañaznzû*
 'hunt≈3'

In conclusion, various verbal morphemes have been compared with case markers and evaluated with respect to the first three of Z&P's criteria to determine their syntactic status.¹⁰ The investigation revealed that while case markers are independent syntactic words, i. e. clitics, most verbal morphemes are suffixes dependent on the predicate.

The illocution and the subject person morphemes fall somewhere in between. While their syntactic distribution points clearly to their Wackernagel clitic status, the presence of gaps in their combinations and their phonological properties are characteristic of affixes.¹¹

	CASE MARKERS	MOST VERBAL MORPHEMES	ILL & PER MORPHEMES
CRITERION A	clitic	affix	clitic
CRITERION B	clitic	affix	affix
CRITERION C	clitic	affix	affix

Functional morphemes by Z&P's criteria.

¹⁰ The latter three of Z&P's criteria pertain to semantics, syntax, and the relative ordering of affixes and clitics. They have generally not been found informative.

CRITERION D

Semantic idiosyncrasies are more characteristic of affixed words than of clitic groups.

CRITERION E

Syntactic rules can affect affixed words, but cannot affect clitic groups.

CRITERION F

Clitics can attach to material already containing clitics, but affixes cannot.

Semantic idiosyncrasies have not been observed among either verbal morphemes or case markers, which renders CRITERION D mute. Syntactic rules relevant to CRITERION E have not been identified. Lastly, the informativity of CRITERION F depends on fact about the linear ordering of morphemes given independent evidence of affixhood or clitichood. CRITERION F cannot tell between two analyses which treat a group of morphemes uniformly as all affixes or all clitics.

¹¹ For a formal account which wrestles with a similar suffix-clitic duality, see Crysmann (2006)'s treatment of Polish person agreement "floating affixes," strikingly parallel in their syntax and morphophonology to A'ingae's subject person morphemes.

4

ANALYSIS

A'ingae exhibits a complex morphophonology, where morphological idiosyncrasies interweave with an unusual phonology of stress assignment. The richness of the system can be gleaned from a minimal six-tuple of verb pairs, showing distinct stress behaviors of six suffix types (1-6). Here, a formal analysis of this complex data pattern will be undertaken.

		a. <i>upathû ...-mbi</i>	b. <i>afase ...-mbi</i>
		'pick ...-NEG'	'insult ...-NEG'
(1)	-'chu	'SBRD'	<i>upáthû-</i> 'chu-mbi
(2)	-'fa	'PLS'	<i>upáthí-</i> 'fa-mbi
(3)	-'ji	'PRCM'	<i>upathû-</i> jí-mbi
(4)	-'je	'IMPV'	<i>upáthû-</i> 'je-mbi
(5)	-'kha	'DMN'	<i>upáthû-</i> 'kha-mbi
(6)	-khu	'RCPR'	<i>upathû-</i> khu-mbi
			<i>afase-</i> chu-mbi
			<i>afase-</i> fa-mbi
			<i>afase-</i> ji-mbi
			<i>afáse-</i> 'je-mbi
			<i>afasé-</i> 'kha-mbi
			<i>afase-</i> khu-mbi

Section 4.1 will introduce the frameworks of Optimality Theory (McCarthy and Prince, 1993; Prince and Smolensky, 1993; others) and Cophonology Theory (Anttila, 1997b; Orgun, 1996; others).

Section 4.2 will distinguish between two classes of verbs—the regular and irregular ones—in a step towards an account of the differences between (1-6a) and (1-6b).

Section 4.3 will present evidence for the existence of two phonological levels—level 0 and level 1—explaining the differences between (2a) and (5), on one hand, and (3a) and (6), on the other.

Section 4.4 will categorize suffixes with respect to their faithfulness to stem stress—as either recessive or dominant—thus accounting for the differences between (1-3b) and (4-6b).

Section 4.5 will further complicate the pattern by considering the role glottal stops play in stress assignment. It will introduce a language-particular prosodic rule, deriving the forms of (1a) and (4).

Section 4.6 will present basic facts of the phonological, morphologically unconditioned, assignment of secondary stress.

Section 4.7 will make a tentative observation about the phonological status of the glottal stop in A'ingae, anticipating future research.

4.1 FRAMEWORKS

The two frameworks I will employ in a formal account of A'ingae morphophonology of stress are Cophonology Theory (Anttila, 1997a; Orgun, 1996; others) and Optimality Theory (McCarthy and Prince, 1993; Prince and Smolensky, 1993; others).

[Section 4.1.1](#) will be devoted to Optimality Theory, a framework in which underlying forms proposed by linguistic analysis are related to the observed surface forms via a mechanism of optimal constraint satisfaction. The phonological functions of Cophonology Theory will be formalized as Optimality Theoretic rankings.

[Section 4.1.2](#) will take up Cophonology Theory (Anttila, 1997a; Orgun, 1996; others), a framework which provides formal tools for integrating phonology and morphology. Cophonology Theory particularizes constraint rankings known from Optimality Theory to morphological constructions, effectively proposing multiple phonological subgrammars within one language's grammar.

4.1.1 *optimality theory*

Optimality Theory is a formal framework which proposes that the observed linguistic forms emerge as a consequence of optimal satisfaction of conflicting constraints (McCarthy and Prince, 1993, 1995; Prince and Smolensky, 1993; others).

The three basic components of the theory are the GENERATOR (GEN), the CONSTRAINT component (CON), and the EVALUATOR (EVAL).

The GENERATOR (GEN) takes an input and generates a set of all candidates (possible outputs) evaluated by EVAL based on CON.

The CONSTRAINT component (CON) is the set of all criteria for choosing among the possible outputs generated by GEN. The criteria are phrased as violable constraints; they are the criteria which EVAL uses to decide between candidates.

The EVALUATOR (EVAL) chooses one optimal candidate from the list generated by GEN based on the ranking of CON.

GEN, the CON and EVAL are assumed by the theory to be universal. Different grammars are the result of different rankings of constraints present in the universal constraint set CON. Cophonology Theory, discussed in [Section 4.1.2](#), extends this idea to language-internal variation, proposing that different morphological constructions can be associated with different phonological subgrammars.

Particular input-output mappings selected by EVAL are commonly represented in form of tableaux, where the candidates generated by GEN are plotted on the x-axis and the constraints of CON are ranked on the y-axis. Consider an example tableau to observe the principles by which constraint evaluation operates.

input:	A »	B »	C,	D
i. output _i	*!			
ii. output _{ii}		**	*!*	*
☞ iii. output _{iii}	**	*	*	

Tableau, an example.

A constraint to the left of the dominates symbol » is ranked above the constraints to its right. A comma , between two constraints indicates that their relative ranking cannot be determined. The violation mark * symbolizes the violation of a constraint by a candidate. The exclamation mark ! to the right of the violation mark additionally indicates that the violation is fatal, i. e. it ultimately eliminates the candidate from the race for optimality. Horizontal rules —— strike out constraint when their evaluation is no longer relevant, i. e. past a fatal violation or after all other candidates have been eliminated. The hand ☞ points to the most optimal candidate.

Constraint evaluation is a step-wise process. First, the highest ranking constraints are evaluated, which means that the violation of a higher-ranking constraint cannot be compensated by the satisfaction of a lower-ranking one (Kager, 1999). Constraint A ranks above constraint B and eliminates candidate i, even though candidates ii and iii accrue twice as many constraint B violations. Constraints past A are stricken out for candidate i, as their evaluation is irrelevant.

When all considered candidates are assigned the same number of violation marks by a constraint, that constraint does not play decisive role in selecting the optimal candidate. Thus, candidates ii and iii which both fair equally poorly with respect to constraint B are further evaluated by the criteria of constraints C and D.

When candidates violate a constraint to different degrees, the candidate with the least number of violations wins. In the example considered, EVAL maps input to output_{iii}. Observe that although constraint C plays the decisive role in picking the winning candidate, constraint D is evaluated as well, as the relative ranking of constraints C and D has not been determined.

Optimality Theory proposes that the set of constraints CON is universal. There are two main types of constraints: FAITHFULNESS constraints and MARKEDNESS constraints. FAITHFULNESS constraints en-

sure the identity between aspects of the input and the output. MARKEDNESS constraints ensure that the output is well-formed, i. e. it conforms with particular demands of the language's grammar. The two classes of constraints are usually particularized to elements of linguistic structure.

FAITHFULNESS and MARKEDNESS constraints are inherently in tension: FAITHFULNESS constraint work to prevent deviations from the input while MARKEDNESS constraints tweak to conform to the language's grammar. Variation in relative importance of particular FAITHFULNESS and MARKEDNESS yields variation in language grammars.

4.1.2 cophonology theory

Cophonology Theory (Anttila, 1997b; Orgun, 1996; others) is a formal framework of phonology-morphology interface in the tradition of unification-based grammar (HPSG: Pollard and Sag, 1994; CG: Fillmore and Kay, 1996; LFG: Kaplan and Bresnan, 1982; others). It builds on the advances made by Lexical Phonology and Morphology (Kiparsky, 1982; Mohanan, 1982; others).

Cophonology Theory models morphologically conditioned phonology by associating morphological processes with phonological subgrammars, or *cophonologies*. The phonological subgrammars are themselves morphologically blind, which predicts that the phonology of a word depends on the phonologies of its constituent parts and their hierarchical organization (Caballero, 2011; Inkelas and Zoll, 2007).

Cophonology Theory models morphemes (such as stems and affixes) as signs and morphological processes as constructions which combine these signs. Each construction is associated with a syntactic SYN category, as well as a meaning SEM and a form PHON function (a cophonology). The rules or constraints which make up the cophonology are general and they themselves do not refer to morphological categories. When these phonological functions differ across morphological constructions, morphology yields language-internal phonological variation (Caballero, 2011; Inkelas and Zoll, 2005, 2007).

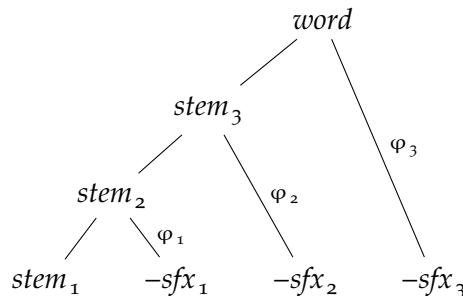

The verb *se'je* 'cure' and the passive suffix *-ye* 'PASS' below are used to exemplify an affixation construction in A'ingae. Boxed indices mark those values whose identity is imposed by the construction.

The left daughter's category is *verb*, while the right daughter's category is *suffix*. The construction is inflectional, which means that the mother node's category is identified with the category of its left daughter. The mother node's SEMANTICS is the output of applying the meaning function of *-ye* 'PASS' to *se'je* 'cure.' Finally, its PHONOLOGY is the output of a construction-specific cophonological function

$\begin{bmatrix} \boxed{1} \verb \\ \text{SEM} & \boxed{2}(\boxed{3}) = \lambda y. \lambda x. \text{cure}' \\ \text{PHON} & \varphi_{\text{je}}(\boxed{4}, \boxed{5}) = [\text{seheje}] \end{bmatrix}$	
$\begin{bmatrix} \boxed{1} \verb \\ \text{SEM} & \boxed{3} \lambda x. \lambda y. \text{cure}' \\ \text{PHON} & \boxed{4} ['\text{se?he}] \end{bmatrix}$	$\begin{bmatrix} \text{inflectional suffix} \\ \text{SEM} & \boxed{2} \lambda f. \lambda x. \lambda y. f(y)(x) \\ \text{PHON} & \boxed{5} [\text{je}] \end{bmatrix}$
An inflectional construction, <i>sejeye</i> 'cure-PASS.'	

whose two arguments are the phonologies of its two daughters. Observe the deletion of stress and the glottal stop in the mother node's form [seheje], a consequence of applying the cophonological function associated with the passive suffix *-ye* 'PASS' to ['se?he] and [je]. The analysis of stress deletion and glottal stop deletion will be given in Sections 4.4 and 4.5.3.

The dependence of a word's phonology on the phonologies of its constituent parts and their hierarchical organization is derived by the very architecture of Cophonology Theory. Since the morphological constructions apply sequentially, complex words have branching structures (Caballero, 2011).

Morphological constituency, an example.

This hierarchical structure has a direct phonological correlate: the phonologies of branching nodes depend exclusively on the phonologies of their daughters. For example, the phonology of the *word* node is the output of the function $\varphi_3(stem_3, -sfx_3)$, blind to the fact that the *stem₃* node is a morphological complex of *stem₂* and *sfx₂*. Likewise, the function φ_2 as applied to its two arguments, *stem₂* and *-sfx₂*, does not have access to information about the nodes which come subsequent to it (*sfx₃* and *word*). In this way, the branching structure of morphologically complex words derives the domains of applicability for particular cophonologies (Caballero, 2011; Inkelas and Zoll, 2007).

Although in principle there is no upper limit on how disparate particular cophonologies within a language can be, Cophonology Theory employs grammar lattices to capture the commonalities among particular cophonologies, with mother nodes abstracting away phonological patterns shared by their daughters. Language-general phonological patterns are captured in the root node. Construction-particular phonological patterns are captured in its inferior nodes.

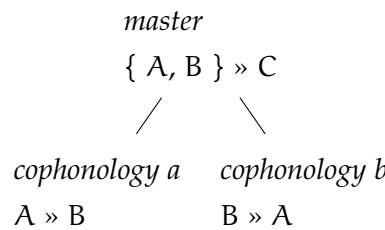

If cophonologies are implemented with Optimality Theoretic constraint rankings, terminal nodes correspond to the cophonologies associated with particular morphological constructions, while their superior nodes correspond to partial constraint rankings capturing the commonalities found among the cophonologies. In particular, the root node corresponds to the constraint rankings determined by the overall phonology of the language. It determines the *master* ranking which holds true of all the constructions in the language.

Consider a hypothetical language with three operative constraints A, B, and C, and two different cophonologies: *cophonology a* associated with the ranking A » B » C and *cophonology b* associated with the ranking B » A » C. Both cophonologies share in common the ranking of A and B above C, while the relative ranking of A and B differs between them.

RANKING	
<i>cophonology a</i>	A » B » C
<i>cophonology b</i>	B » A » C

Terminal nodes of a lattice, an example.

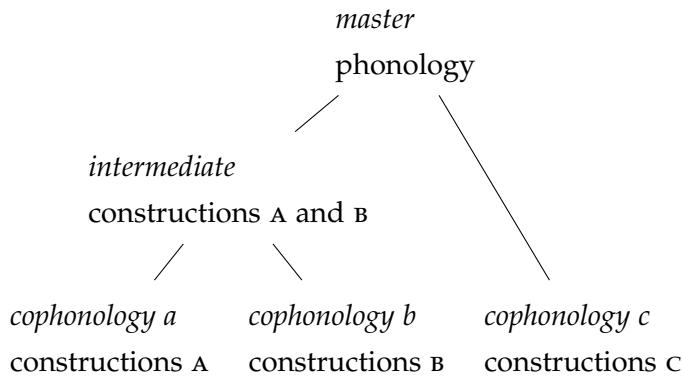

The observed commonality can be captured in the *master* ranking as { A, B } » C. Is it then only necessary to say that *cophonology a* ranks A above B and that *cophonology b* ranks B above A; the ranking of A and B relative to C is determined by a node from which both cophonologies inherit.

Grammar lattice, an example.

Distinct cophonologies correspond to terminal nodes and capture patterns specific to morphological constructions. The *master* ranking

corresponds to the root node and captures the language's overarching phonology. Commonalities found among morphological constructions which do not generalize to the overarching phonology of the language can be captured with intermediate-level rankings.

Grammar lattice, a schema.

To fully capture the commonalities found among A'ingae functional morphemes in the analysis to follow, I will employ a multiple inheritance hierarchy. To see the utility of multiple inheritance hierarchies, consider a hypothetical language with four operative constraints A, B, C, and D, and four cophonologies, which have the following property: all four cophonologies rank A and B above C and D, but across the four cophonologies, all combinations of relative rankings of A with respect to B and C with respect to D are attested. This is to say, the four cophonologies form a 2×2 matrix whose one dimension specifies the relative rankings of A and B while the other specifies the relative ranking of C and D.

	A » B	B » A
C » D	cophonology ac A » B » C » D	cophonology bc B » A » C » D
D » C	cophonology ad A » B » D » C	cophonology bd B » A » D » C

Terminal nodes of a multiple inheritance lattice, an example.

The relative rankings of A with respect to B and C with respect to D can be conceptualized as two language internal phonological parameters which vary independently. A parametric variation of this sort characterizes A'ingae, which will be motivated in the following sections of this chapter.

A multiple inheritance hierarchy can formally capture this pattern of intersecting commonalities, as terminal nodes are allowed to inherit

from multiple intermediate nodes. All nodes ultimately inherit from the root node, which specifies the *master* ranking.

Multiple inheritance lattice, an example.

Although multiple-inheritance matrices are proposed in some unification-based grammars (e.g. SBCG: Boas and Sag, 2012)—a tradition from which Cophonology Theory inherits, their employment in a Cophonological analysis is—to the best of my knowledge—novel.

4.2 VERBAL CLASSES

Most A'ingae verbal stems are bi- or trisyllabic. Due to their number, they are the most informative about the language's prosodic processes. Some verbal stems are monosyllabic; from them, little can be gleaned about the stress system, so they will be referred to only in passing. The occasional quadrисyllabic oddballs are all lexicalizations of morphologically complex forms and are all irregularly stressed.

In the morphologically simplex, bare forms of bisyllabic verbs, stress falls uniformly on the penultimate syllable (48).

UNIFORM PENULTIMATE STRESS

-
- (48) a. *pánza* b. *fétha* c. *áfa* d. *páña*
 'hunt' 'open' 'speak' 'hear'

In bare forms of trisyllabic verbs, stress falls predominantly on the penultimate syllable (49a-b), but there are a small number of verbs with word-initial stress (49c-d).

PENULTIMATE STRESS	WORD-INITIAL STRESS
--------------------	---------------------

- | | | | |
|-----------------------|------------------|-----------------|-------------------|
| (49) a. <i>upáthû</i> | b. <i>agáthu</i> | c. <i>áfase</i> | d. <i>kúndase</i> |
| 'pick' | 'count' | 'insult' | 'tell' |

Bisyllabic verbs further subdivide with respect to stress in morphologically complex forms. Most of the language's suffixes shift the stress

of bisyllabic verbs rightwards (48a-b), yielding penultimate stress on morphologically simplex and suffixes forms alike, as demonstrated with the precumulative *-ji* 'PRCM' (50a-b) and the irrealis *-ya* 'IRR' (51a-b). Some verbs, however (48c-d), resist the shift, retaining word-initial stress (50-51c-d).

	PENULTIMATE STRESS		WORD-INITIAL STRESS	
(48)	a. <i>pánza</i>	b. <i>fétha</i>	c. <i>áfa</i>	d. <i>páña</i>
	'hunt'	'open'	'speak'	'hear'
(50)	a. <i>panzá-ji</i>	b. <i>fethá-ji</i>	c. <i>áfa-ji</i>	d. <i>páña-jin</i>
	'hunt-PRCM'	'open-PRCM'	'speak-PRCM'	'hear-PRCM'
(51)	a. <i>panzá-ya</i>	b. <i>fethá-ya</i>	c. <i>áfa-ya</i>	d. <i>páña-ña</i>
	'hunt-IRR'	'open-IRR'	'speak-IRR'	'hear-IRR'

The above difference between stress-shifting (48a-b) and rigid-stress (48c-d) bisyllabic verbs is paralleled among trisyllabic verbs, whereby penultimate stress (49a-b) shifts down to the penultimate syllable when the verb is suffixed (52-53a-b), but word-initial stress (49c-d) remains word-initial under those same circumstances (52-53c-d).

	PENULTIMATE STRESS		WORD-INITIAL STRESS	
(49)	a. <i>upáthû</i>	b. <i>agáthu</i>	c. <i>áfase</i>	d. <i>kúndase</i>
	'pick'	'count'	'insult'	'tell'
(52)	a. <i>upatú-ji</i>	b. <i>agathú-ji</i>	c. <i>áfase-ji</i>	d. <i>kúndase-ji</i>
	'pick-PRCM'	'count-PRCM'	'insult-PRCM'	'tell-PRCM'
(53)	a. <i>upatú-ya</i>	b. <i>agathú-ya</i>	c. <i>áfase-ya</i>	d. <i>kúndase-ya</i>
	'pick-IRR'	'count-IRR'	'insult-IRR'	'tell-IRR'

Thus, the language's verbs can be divided in two classes with respect to patterns of stress shift, irrespective of the number of syllables: one with a pattern of penultimate stress (48-49a-b), the other with a pattern of initial stress (48-49c-d).

The difference between penultimate-patterning verbs (48-49a-b) and initial-patterning verbs (48-49c-d), I propose, can be attributed to a difference in the mechanism of stress assignment. Initial stress is lexical; penultimate stress is supplied by the language's phonology in the absence of lexical stress. In short, initial-patterning verbs have stress at the underlying level (48'-49'c-d), which the penultimate-patterning verbs lack (48'-49'a-b).

	PHONOLOGICAL STRESS		LEXICAL STRESS	
(48 ¹)	a. /panza/ [pán̥za] ‘hunt’	b. /fetha/ [fétha] ‘open’	c. /áfa/ [áfa] ‘speak’	d. /páñ̥a/ [páñ̥a] ‘hear’
(49 ¹)	a. /upathû/ [upáthû] ‘pick’	b. /agathu/ [agáthu] ‘count’	c. /áfase/ [áfase] ‘insult’	d. /kíindase/ [kúndase] ‘tell’

Penultimate stress is, in a sense, the language’s default assigned to verbs without lexical stress. I will therefore refer to the lexically stressless verbs (48-49a-b) as *regular*. Initial stress needs to be separately specified. I will refer to the lexically stressed verbs (48-49c-d) as *irregular*.

Regular verbs (48¹-49¹a-b) surface with penultimate stress as a consequence of *culminativity*, a metrical property such that one syllable within the word must carry the primary stress and at most one can. Accentual culminativity is overwhelmingly common in the world’s languages (Alderete, 1999; Hayes, 1995; Liberman and Prince, 1977).

An immediate alternative to the above penultimate-as-default analysis would be one of the opposite markedness profile: take the initial-patterning verbs as regular or representative of the language’s accentual default and the penultimate-patterning verbs as irregular or carrying some form of lexical specification. There are four principal reasons why this initial-as-default analysis is dispreferred to the penultimate-as-default analysis I champion.

First, while initial-patterning bisyllabic verbs are fairly common, only a few initial-patterning trisyllabic verbs have been identified,¹ suggesting that initial stress is more marked than penultimate stress.

Second, all the initial-patterning trisyllables seems to have been historically derived from initial-patterning bisyllables,¹ sometimes via semantically opaque morphology (54-55), suggesting the initial stress pattern can be attributed at least in part to its diachrony.

- | | | |
|------|--|---|
| (54) | a. <i>áfa</i>
‘speak’ | b. <i>kúnda</i>
‘let know’ |
| (55) | a. <i>áfa-se</i>
‘speak-SE’
“insult” | b. <i>kúnda-se</i>
‘let know-SE’
“tell” |

Third, taking penultimate stress as the language’s default leads to a more parsimonious analysis. With default penultimate stress, initial

¹ Trisyllables with glottal stops are excluded here, as their consistent initial stress is accounted for independently in Section 4.5.3.

stress can be analyzed as a simple matter of faithfulness to the input (to be developed below). If word-initial stress were taken as the default, though, accounting for the shifting penultimate stress would require more intricate mechanisms.

Fourth, all monosyllables are penultimate-patterning; no monosyllables are initial-patterning. This can be demonstrated only with multiply-suffixes verbal forms, whose analysis is given in [Section 4.3](#). Nevertheless, a preanalytical illustration is still possible.

	PENULTIMATE	PENULTIMATE	WORD-INITIAL
(56)	a. <i>an-jín-ña</i> ‘eat–PRCM–IRR’	b. <i>panza-ji-ya</i> ‘hunt–PRCM–IRR’	c. <i>áfa-ji-ya</i> ‘speak–PRCM–IRR’

Monosyllables surface with penultimate stress when suffixed with both *-ji* ‘PRCM’ and *-ya* ‘IRR’ (56a). In doing so, they show affinity to the regular *panza* ‘hunt,’ which likewise surfaces with penultimate stress (56b), and a dissimilitude from the irregular *afa* ‘speak,’ whose word-initial lexical stress surfaces untrammeled (56c). This again suggests that initial stress is more marked than penultimate stress.

The penultimate stress default will be derived as an interaction of two Optimality Theoretic constraints. Those constraints will be motivated in [Section 4.3](#), where data of greater morphological complexity will be discussed. For now, penultimate stress will be captured with a temporary constraint aptly dubbed PENULTIMATESTRESS.

PENULTIMATESTRESS, or $\acute{o}\sigma\#$, temporary

The penultimate syllable is the prosodic head of the word.

Glyphs introduced along with the constraints names, such as $\acute{o}\sigma\#$ above, will be used in the tableaux for shorthand.

PENULTSTRESS ($\acute{o}\sigma\#$) is not a serious theoretical proposal. The constraint is a placeholder used before penultimate stress is derived from the interaction of more fundamental principles in [Section 4.3](#).

Faithfulness to the lexical specification of the initial-stress verbs is guaranteed by a MAXIMALITY constraint which prohibits the deletion of stress (McCarthy and Prince, [1995](#)).

MAXIMALITY(STRESS), or $Mx\acute{o}$

Stress is not deleted.

The data pattern of (48–53) is derived by ranking MAXSTRESS ($Mx\acute{o}$) over PENULTSTRESS ($\acute{o}\sigma\#$), thus preserving exceptional word-initial accentuation, but allowing for penultimate stress to emerge when no lexical stress is present. The ranking of MAXSTRESS ($Mx\acute{o}$) over PENULTSTRESS ($\acute{o}\sigma\#$) is captured in following grammar lattice.

master

Mxó » óσ#

Grammar lattice, 1st iteration.

Since no constructions-specific cophonologies have been proposed yet, the proposed constraint ranking is listed under the *master* node. The ranking is currently predicted to operate in every nook and cranny of the language's phonology, although this will soon be revised. Since only two constraints and one ranking have been introduced so far, the current lattice is understandably minimalist. As refinements to the constraint rankings are being motivated, new iterations of the grammar lattice will be constructed.

Penultimate-stress verbs do not have accentual specification in the input. MAXSTRESS (Mxó) is not violated by any candidate, so the responsibility of picking the winning one rests on PENULTSTRESS (óσ#), as can be seen in (49'a) and (52'a) alike.

(49') a. *upathû:* Mxó » óσ#

- i. *upathû* * - ii. *úpathû* * -  iii. *upáthû*
 - iv. *upathû́* *
-

'pick'

(52') a. *upathûji:* Mxó » óσ#

'insult–PRCM'

In summary, two stress-wise verbal classes have been observed: penultimate-patterning verbs and initial-patterning verbs. Penultimate-patterning verbs have been analyzed as regular, or lexically stressless. Initial-patterning verbs—as irregular, or lexically stressed. PENTULT STRESS (óσ#) has been tentatively proposed to account for the grammatically default penultimate stress. It is dominated by MAXSTRESS, which ensures faithfulness to the word-initial stress of irregular verbs.

4.3 PHONOLOGICAL LEVELS

As demonstrated in [Chapter 3](#), inflection of the A'ingae verb is extraordinarily rich, with a dozen or so morphological slots, many of which can be occupied at the same time. This section will consider two complications involving multiply-suffixed verbal forms and polysyllabic suffixes and propose a revision to the analysis of [Section 4.2](#).

[Section 4.2](#) showed that accentually unmarked verbs, such as *panza* 'hunt,' surface with penultimate stress when unsuffixed and suffixed alike. Forms with the precumulative *-ji* 'PRCM' and the unrealis *-ya* 'IRR' are reiterated below (57). Multiply-suffixed verbal forms present a complication to this picture: when a second suffix is attached, here the negative *-mbi* 'NEG,' forms with *-ji* 'PRCM' and *-ya* 'IRR' differ in the placement of stress (58). Forms suffixed with *-ji* 'PRCM' undergo a rightward stress shift and surface with penultimate stress again (58a), whereas forms suffixed with *-ya* 'IRR' retain the stem-final stressed position and surface with antepenultimate stress (58b).

	PENULTIMATE STRESS	STEM-FINAL STRESS
(57)	a. <i>panzá-jí</i> 'hunt-PRCM'	b. <i>panzá-ya</i> 'hunt-IRR'
(58)	a. <i>panza-ji-mbi</i> 'hunt-PRCM-NEG'	b. <i>panzá-ya-mbi</i> 'hunt-IRR-NEG'

Lexically stressed verbs, such as *áfa* 'speak,' behave in a less unexpected way, with stress initial across the board (59–60). These lexically stressed verbs will play a secondary role in the analysis developed throughout this section; interactions of lexical stress specification with diacritic properties of the language's functional morphemes will be taken up again in [Section 4.4](#).

	UNIFORM WORD-INITIAL STRESS	
(59)	a. <i>áfa-ji</i> 'speak-PRCM'	b. <i>áfa-ya</i> 'speak-IRR'
(60)	a. <i>áfa-ji-mbi</i> 'speak-PRCM-NEG'	b. <i>áfa-ya-mbi</i> 'speak-IRR-NEG'

The second complication involves polysyllabic suffixes. There are two bisyllabic inflectional morphemes: the apprehensional *-sa'ne* 'APPR' and the prohibitive *-jama* 'PRHB.' Both suffixes trigger antepenultimate stress on regular verbs (61).

	ANTEPENULTIMATE STRESS	
(61)	a. <i>panzá-sa'ne</i> 'hunt-APPR'	a. <i>panzá-jama</i> 'hunt-PRHB'

The two complications outlined above require a refinement to the analysis proposed in [Section 4.2](#). The refined analysis can be informally summarized as follows: penultimate stress is the default; all the suffixes are classified in one of two groups based on their accentual properties.

As before, stress is assigned to the penultimate syllable by default. This default pattern emerges whenever a verb is not assigned stress at an earlier stage via morphological means.

Unlike before, suffixes are divided in two groups with respect to their accentual properties. One group is *nonstressing*—these suffixes do not contribute any stress, but they do form part of the accentual domain and are taken into account when the default penultimate stress is assigned to lexically stressless verbs. The other group is *prestressing*—these suffixes place stress on the right edge of the stem to which they

attach (on the syllable immediately to their left), effectively contributing lexical stress. Prestressing is blocked if the stem has lexical stress as an irregular verb or due to having previously undergone prestressing suffixation.

The precumulative *-ji* 'PRCM' is a nonstressing suffix, whereas all the other functional morphemes introduced so far: the negative *-mbi* 'NEG,' the unrealis *-ya* 'IRR,' the apprehensional *-sa'ne* 'APPR,' as well as the prohibitive *-jama* 'PRHB,' are prestressing.

The nonstressing suffix *-ji* 'PRCM' attaches before the prestressing suffixes. An empirical investigation reveals that the nonstressing suffixes all attach before the prestressing suffixes. As such, the two groups of suffixes can be thought of as reflecting two phonological levels (Kiparsky, 1982). I will therefore say that the nonstressing suffixes attach at level 0, and label the cophonology which corresponds to it as *level 0* or φ_0 . I will say that the prestressing suffixes attach at level 1, and label the cophonology which corresponds to it as *level 1* or φ_1 .²

The updated morphological template on the following page uses subscripts to indicate the phonological level of each suffix. The linear precedence of level 0 suffixes is further highlighted by coloring the morphological slots they occupy in grey.³

The outputs of level 0 and level 1 suffixal constructions are *lexical words*. A lexical word can be stressed by virtue of having a lexically stressed (irregular) root, or by having a prestressing (level 1) suffix. If neither obtains, the word is lexically stressless. A *prosodic word* is required to have exactly one accent (see the discussion of culminativity in Section 4.2). If a lexical word is stressless, it is supplied with penultimate stress to comply with the language's prosodic requirements.

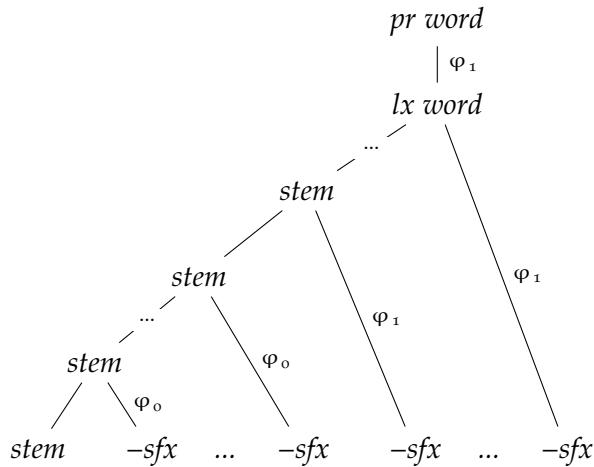

Penultimate stress will be formalized with the level 1 cophonology. This is to say, the prestressing of level 1 suffixes and the default penultimate stress will be unified and captured with one constraint ranking. The constraint ranking will have the effect of deriving stem-final stress in binary constructions involving a stem and a level 1 suffix and penultimate stress in unary construction involving only a stem

² Phonological layering is not imposed by the architecture of the Cophonology Theory. This predicts the existence of languages without phonological levels. The prediction is borne out by, for example, Turkish (Orgun, 1996). Nevertheless, in languages where phonological levels are a reality, the Cophonology Theory allows for capturing it with a LEVEL feature, whose value is appropriately restricted in lower-level constructions. For details of the implementation, see Orgun (1996).

³ The verbal diminutive *-kha* 'DMN' is somewhat of an outlier—the only level 1 morpheme in a slot of level 0 suffixes. Nevertheless, its aspectual semantics cements its position in the template.

On one hand, the verbal diminutive *-kha* 'DMN' does not violate the proposed morphological layering, as no level 0 suffix attaches past it. On the other, its realization is somewhat variable: it has a glottalless variant *-kha* 'DMN' which is realized as a level 0 suffix, possibly by analogy with other aspectual morphemes.

(prosodic words). The morphological constituency below schematizes the claims made in preceding paragraphs.

Morphological constituency, 1st iteration.

Levels 0 and 1 will be formalized as two Optimality Theoretic constraint rankings. Level 0 suffixes do not insert stress. To capture this, a DEPENDENCE constraint is introduced (McCarthy and Prince, 1995). The constraint is temporary; it will be replaced with a superordinate constraint preventing the insertion of metrical structure in general in [Section 4.6](#).

DEPENDENCE(STRESS), or DP σ , temporary
Stress is not epenthesized.

DEPSTRESS (DP σ) is ranked in the level 0 cophonology above constraints which supply stress at level 1 (to be discussed momentarily) to ensure faithful mappings of stressless input to stressless output.

Level 1 suffixes stress the final syllable of the domain to which they attach. This can be straightforwardly captured with an ALIGNMENT constraint of McCarthy and Prince (1993)'s Generalized Alignment framework. The constraint aligns stress with the right edge of the stem, effectively deriving the prestressing of level 1 suffixes.

ALIGN(STEM, R, STRESS, R), or $\sigma]$

The stem-final syllable is the prosodic head of the word.

ALIGNSTEM ($\sigma]$) ranks above DEPSTRESS (DP σ), because it supplies stress to stressless stems. ALIGNSTEM ($\sigma]$) ranks below MAXSTRESS (Mx σ) introduced in [Section 4.2](#), because it does not do so when stress is already present.

Primary stress is placed on the penultimate syllable in the absence of lexical contraindications. This is captured, as anticipated, with the same constraint ranking as the prestressing of level 1 suffixes. To

achieve this, a **NONFINALITY** constraint (Prince and Smolensky, 1993) which prevents the placement of stress on the word-final syllable is ranked above **ALIGNSTEM** ($\delta]$). This ranking predicts stem-final stress with level 1 suffixes and penultimate stress on lexically stressless words.

NONFINALITY, or $^{\delta}\#$

The final syllable of a word is not its prosodic head.

NONFINALITY ($^{\delta}\#$) is inactive with level 1 suffixes, as prestressing means that stress does not surface on the word-final syllable either way. When applied to a fully inflected yet lexically stressless word, though, it makes all the difference: in a unary construction with no suffixation, the domains of word and stem coincide. As a result, **ALIGNSTEM** ($\delta]$) targets the entire word. **ALIGNSTEM** ($\delta]$) is interpreted in a gradient fashion: one violation mark is assigned for each syllable between stress and the right edge of the word, so the constraint pushes for word-final stress. Dominated by **NONFINALITY** ($^{\delta}\#$), however, it settles for the second best, which is penultimacy.⁴

Finally, **LEXICALWORD**≈**PROSODICWORD** operative at level 1 ensures that every lexical word corresponds to a prosodic word.

LEXICALWORD≈**PROSODICWORD**, or $\#\omega\#$

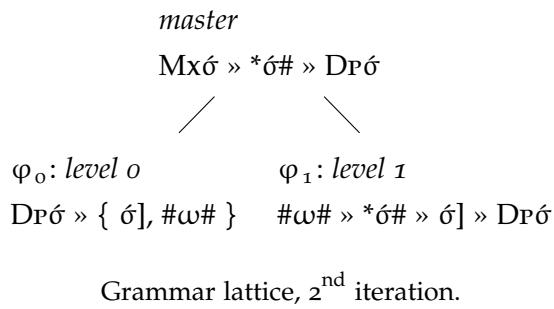

Every lexical word corresponds to a prosodic word.

LxWD≈**PrWD** ($\#\omega\#$) forces every word to have at least one foot. In practice, this boils down to eliminating stressless candidates. **LxWD**≈**PrWD** ($\#\omega\#$) ranks above **NONFINALITY** ($^{\delta}\#$), ensuring that monosyllabic words, whose all syllables are word-final, can be parsed as well. A revised grammar lattice graphs the refinements discussed in the preceding paragraphs.

The *master* cophonology ranks the faithfulness constraints and **NONFINALITY** ($^{\delta}\#$) generally operative in the language. The ranking of **MAXSTRESS** ($Mx\delta$) above **NONFINALITY** ($^{\delta}\#$) will be shortly motivated towards the end of the section. The *level 0* cophonology ranks **DEPSTRESS** ($DP\delta$) above constraints which favor prosodic structure, reflecting the fact that level 0 suffixes are nonstressing. The *level 1* cophonology ranks **ALIGNSTEM** ($\delta]$) below **NONFINALITY** ($^{\delta}\#$) and

⁴ Alternatively, one could separate the rankings for level 1 stem-final stress and prosodic word penultimate stress and derive the penultimate stress of the prosodic word constructing metrical structure bottom-up. In this approach, syllables are parsed into trochees from right to left (see Section 4.6) and primary stress is assigned via some Optimality Theoretic equivalent of the **ENDRULERIGHT** (Hayes, 1995), e.g. an **ALIGNMENT** constraint (McCarthy and Prince, 1993).

This alternative is viable, but it would not buy us any simplicity: it increments the number of proposed cophonologies by one, and does not reduce the number of invoked constraints. **ALIGNSTEM** ($\delta]$) is independently necessitated by level 1 suffixes, and **NONFINALITY** ($^{\delta}\#$) would have to be invoked any way to explain why heavy-final words do not receive ultimate stress (see the footnote on page 71).

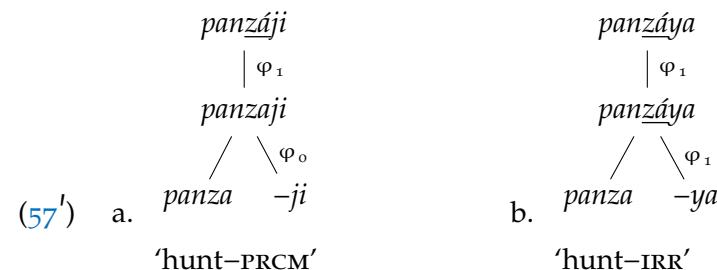

above DEPSTRESS ($\text{D} \sigma \sigma$), which captures level 1 prestressing and prosodic word penultimate stress.

Technically, each node in a grammar lattice has the exact same set of constraints, with subordinate nodes resolving ranking indeterminacies of the superordinate nodes. The constraints not listed under the *master* node, i. e. ALIGNSTEM ($\sigma]$) and LxWD≈PRWD ($\# \omega \#$), are still understood to be present there. They are skipped to visually declutter the lattice. The ranking $\text{Mx} \sigma \gg * \sigma \# \gg \text{D} \sigma \sigma$ can therefore be understood to stand for $\text{Mx} \sigma \gg * \sigma \# \gg \text{D} \sigma \sigma, * \sigma \#, \# \omega \#$, with the latter two constrains unranked with respect to the former three. Due to the ultimate resolution of *master* into *level 0* or *level 1*, the notational convention I am adopting does not result in a loss of formal precision.

The two constraint rankings *level 0* and *level 1* suffice to account for the data presented this far. The penultimate stress identified in [Section 4.2](#) is the output of level 1 cophonology applied at one of two stages: suffixation or the prosodic word.

In verbal forms suffixed at level 0, lexical stress is absent, so penultimate stress is supplied at the prosodic word level in a unary level 1 construction ([57](#)'a).

In verbal forms suffixed at level 1, on other other hand, stress is lexical, as level 1 suffixes stress the syllable immediately to their left. A subsequent reapplication of the level 1 cophonology in a unary construction simply preserves that stress, since prestressing is blocked by preexisting stress ([57](#)'b). For monosyllabic suffixes, this coincides with penultimacy.

The tableaux below demonstrate the evaluation of four candidates each against two constraint rankings applied sequentially (57^{"a-b}). Brackets delimit input stems. The cophonology active in any construction is given by the subscript to the right of the input. The constraint rankings associated with particular cophonologies are additionally labeled as such in the top row. The succeeds operator $>$ relates the output of one cophonology to the input of the next one.

With faithfulness constraints dominating $LxWD \approx PRWD (\#\omega\#)$, the output of a level 0 construction is stressless given stressless input. That output then becomes input to a level 1 construction, where it is assigned penultimate stress in a contest between the gradient ALIGN STEM (σ) pushing for stem-final stress (here word-final as well) and the absolute NONFINALITY (* $\sigma\#$) penalizing word-final stress (57^{"a}).

level 0					
(57 ["])	a.	[panza]ji _{0:}	Mx σ »	* $\sigma\#$ »	DP σ »

	iii.	<i>panzáji</i>		*	
	iv.	<i>panzají</i>		*!	

'hunt-PRCM'

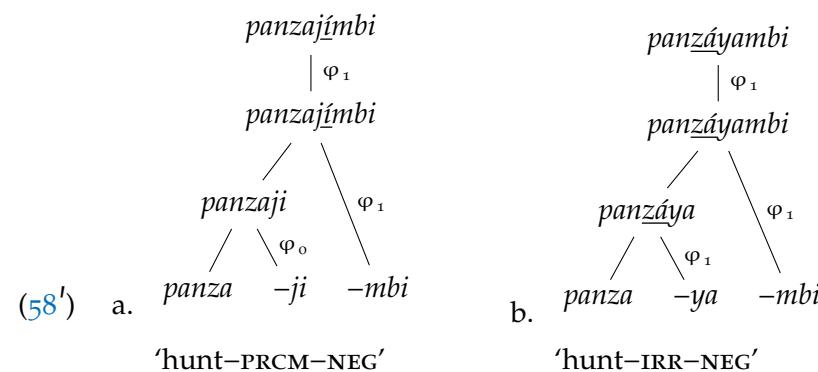

Ranking ALIGNSTEM (σ) above DEPSTRESS (DP σ) models the pre-stressing behaviour of level 1 suffixes. The repeated application of level 1 cophonology to the output simply preserves the lexical stress from the previous construction (57^{"b}).

☞	iii.	panzáya			*	—————
	iv.	panzayá	*!	—————		

'hunt-IRR'

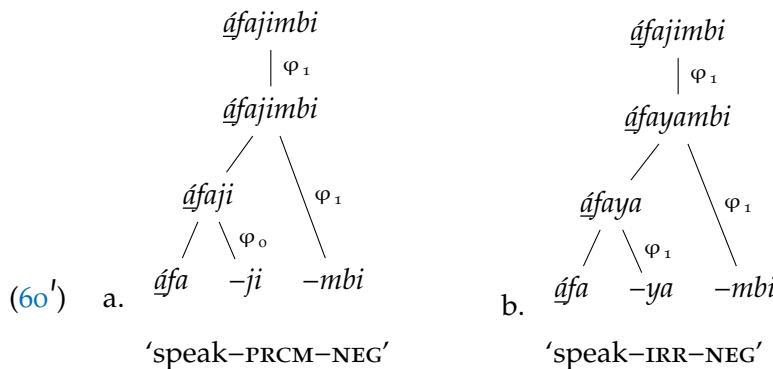

Default stress assignment and level 1-induced prestressing both yield penultimate stress when only one monosyllabic suffix is attached to a bare verb. In multiply-suffixed forms, the two can be told apart: an early attachment of a level 0 suffix does not block the prestressing of a later-attaching level 1 suffix (58'a), whereas stress once induced by a level 1 suffix blocks the prestressing of latter level 1 suffixes (58'b).

That the prestressing associated with level 1 suffixes is blocked for all level 1 suffixes other than the first one is most conspicuous when many of them are attached, as the stress reliably falls on the syllable immediately preceding the first level 1 suffix (62).

The blocking of prestressing seen in (58'^b, 62), where the stress triggered by an earlier applying *-ya* ‘IRR’ blocks the stress associated with *-mbi* ‘NEG,’ is not particular to a configuration of multiple level 1 suffixes. The same mechanism operates when a level 1 suffix attaches to a verb with lexical word-initial stress (60'^l), or whenever level 1 cophonology applies to words that already underwent it (57'^b, 58'^l, 61'^l) To put it differently, prestressing associated with level 1 suffixes is blocked when the stem to which they attach is already accented, regardless of the accent’s provenance.

The tableau below demonstrates the blocking of prestressing in *áfaji* ‘speak–PRCM,’ the first step in the derivation of (60'a).

level 1						
(50')	c.	[áfa]ji ₁ :	Mx́,	#ω# »	*ó# »	́»
i.	<i>afaji</i>	*!	*!	—————		
II	ii. <i>áfaji</i>			*	—	
iii.	<i>afáji</i>	*!		—————		
iv.	<i>afají</i>	*!		—————		

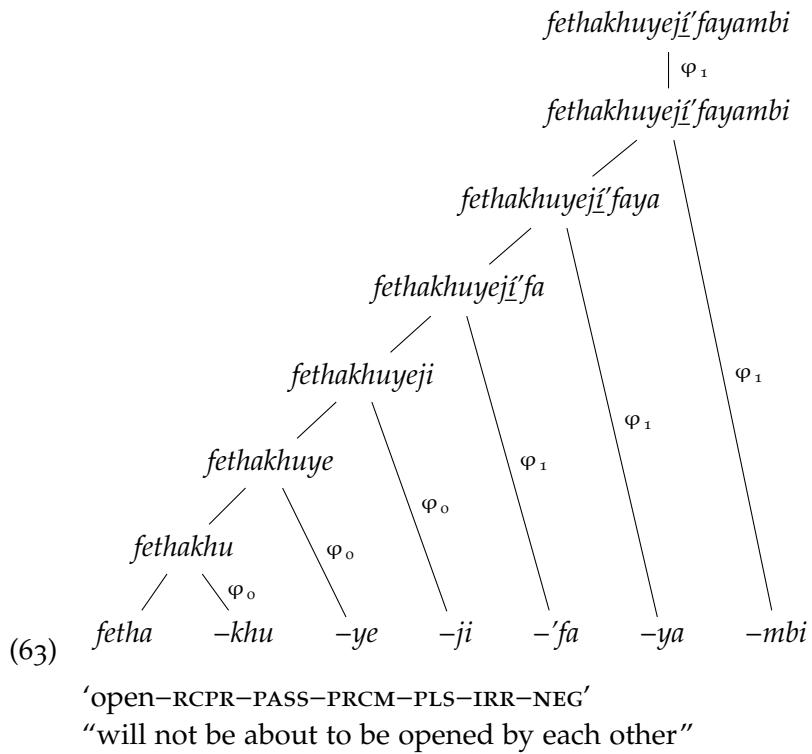

‘speak–PRCM’

Indeed, no other pattern could be observed. The architecture of Cophonology Theory necessitates that the cophonologies be morphologically blind (Orgun, 1996). This is to say, morphological constructions have no access to the morphological makeup of the stem, so if the stem retains its accent, it will do so regardless of how it got there.

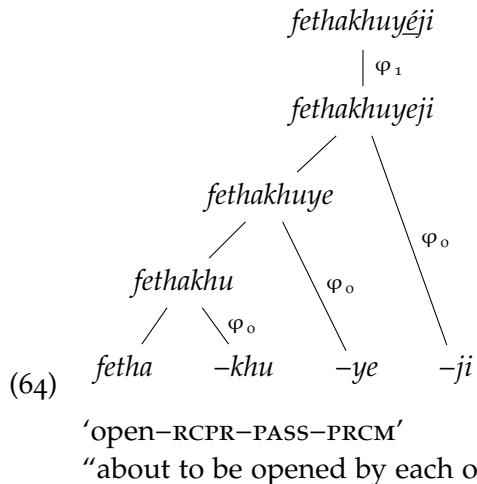

Finally, the refined analysis also accounts for the antepenultimate stress of the two bisyllabic suffixes *-sa'ne* ‘APPR’ and *-jama* ‘PRHB.’ As level 1 morphemes, the antepenultimacy follows straightforwardly from their prestressing (61').

	<i>panzásá'ne</i>		<i>panzájama</i>
	φ ₁		φ ₁
	<i>panzásá'ne</i>		<i>panzájama</i>
	/ \ φ ₁		/ \ φ ₁
(61')	a. <i>panza</i> <i>-sa'ne</i>	b. <i>panza</i> <i>-jama</i>	
	‘hunt–APPR’		‘hunt–PRHB’

The principles demonstrated above generalize fully to forms of any morphological complexity. They are most conspicuous in verbs with many level 0 and level 1 suffixes, where the nonstressing behavior of the former and the blockable prestressing of the latter collaborate to mark the left boundary between the two phonological levels (63).

This can be contrasted with simpler morphological form, composed only of a stressless verb with level o suffixes, where stress is supplied by the language's phonology to the penultimate syllable (64).

Finally, two closing remarks about the ranking of NonFINALITY (*ó#). The constraint is present in the master ranking to reflect the language's general dispreference for word-final stress. No verbs with final stress have been reported (pace F&H) and all the reported final-stress nouns, which can be counted on one hand, are borrowings or onomatopoeiae.

MAXSTRESS (Mxó) ranks above NonFINALITY (*ó#) in recognition of those few rare ultimate-stress borrowings or onomatopoeiae. Such a

ranking correctly predicts that word-final stress, however marked it be, is preserved and can surface (65).

(65)	<i>tûntûn:</i>	Mxó »	*ó# »	Dpó
i.	<i>tûntûn</i>	*!	_____	
ii.	<i>tíntûn</i>	*!	_____	
III	<i>tûntûn</i>	*	—	

‘trumpeter finch’

In summary, two phonological levels have been proposed, each associated with a cophonology: *level 0* and *level 1*. Level 0 corresponds to early-attaching suffixes. Level 1 corresponds to late-attaching suffixes and the penultimate stress supplied to stressless verbs by default.

The *level 0* cophonology ranks stem faithfulness above LxWD≈PrWD (#ó#), preventing stress epenthesis. The *level 1* cophonology ranks NONFINALITY (*ó#) above ALIGNSTEM (ó]) and DEPSTRESS (Dpó), resulting in stem-final stress in binary constructions (suffixation) and penultimate stress in unary constructions (prosodic default).

4.4 STEM FAITHFULNESS

Section 4.3 introduced phonological layering of A'ingae by contrasting the accentual demands made by two levels of suffixes: level 0 and level 1. The verbal stems used for the purposes of this demonstration have largely come from the regular, lexically stressless class. The irregular, lexically stressed verbs demonstrate the existence of a further split among the level 0 suffixes.

Level 0 suffixes do not supply stress when they apply to regular, lexically stressless stems (66a-b). As consequence, level 0-suffixed verbs and bare stems alike surface with the default penultimate stress (66-68a-b). When applied to inherently stressed verbs (66c-d), level 0 suffixes fork: some suffixes, such as the precumulative -ji 'PRCM', remain faithful to the stem's stress (67c-d), while others, such as the passive -ye 'PASS' disregard it, allowing for the penultimate stress to surface on irregular verbs (68c-d), equalizing them with the regulars (68a-b).

	STRESSLESS STEM		STRESSED STEM	
(66)	a. <i>pánza</i> 'hunt'	b. <i>agáthu</i> 'count'	c. <i>áfa</i> 'speak'	d. <i>kúndase</i> 'tell'
(67)	a. <i>panzá-ji</i> 'hunt-PRCM'	b. <i>agathú-ji</i> 'count-PRCM'	c. <i>áfa-ji</i> 'speak-PRCM'	d. <i>kúndase-ji</i> 'tell-PRCM'
(68)	a. <i>panzá-ye</i> 'hunt-PASS'	b. <i>agathú-ye</i> 'count-PASS'	c. <i>afá-ye</i> 'speak-PASS'	d. <i>kundasé-ye</i> 'tell-PASS'

Attaching another suffix to passivized verbs *-ye* 'PASS' demonstrates that formulating the pattern in terms of equalizing regular and irregular verbs is on the right track, as both lexically stressed (69a-b) and stressless (69c-d) stems surface with penultimate stress.

	UNIFORM PENULTIMATE STRESS			
(69)	a. <i>panza-yé-mbi</i> 'open-PASS-NEG'	b. <i>agathu-yé-mbi</i> 'count-PASS-NEG'	c. <i>afa-yé-mbi</i> 'speak-PASS-NEG'	d. <i>kundase-yé-mbi</i> 'tell-PASS-NEG'

The passive *-ye* 'PASS', therefore, not only abstains from supplying lexical stress—it deletes the stress of the stem to which it attaches. In the typological literature, suffixes which impose their accentual demands over faithfulness to the stem have gone under the name of *dominant*. Suffixes which prioritize faithfulness to the stem over their own accentual specification have been referred to as recessive (Alderete, 1999; Halle and Vergnaud, 1987; others). In A'ingae, dominance is exemplified by *-ye* 'PASS'; recessiveness—by *-ji* 'PRCM'. Thus, *level o* suffixes further subdivide between recessive and dominant. I will refer to cophonology of the former as *level o recessive* or φ_o and to the cophonology of the latter *level o dominant* or φ_o^\times . The cross \times symbolizes stress deletion associated with dominance.

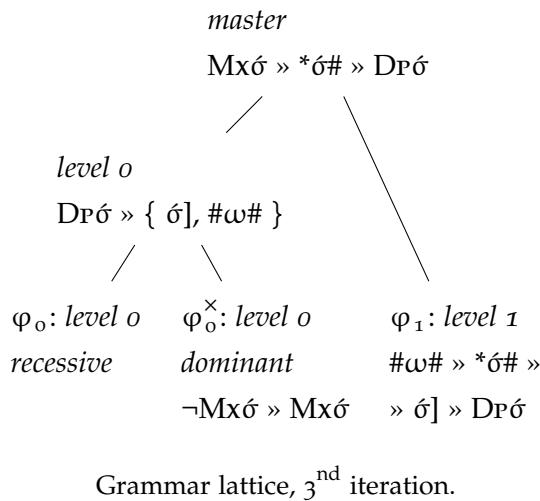

For purposes of concreteness, I will capture the pattern of primary stress deletion with a constraint within Alderete (1999)'s framework of Transderivational Antifaithfulness. In particular, I adopt an ANTI-MAXIMALITY constraint which requires a violation of its positive counterpart MAXSTRESS (Mx δ), whenever stress is present.⁵

ANTI-MAXIMALITY(STRESS), or $\neg Mx\delta$
Stress is deleted.

⁵ Alternatively, this could be rephrased with a *STRESS constraint, which prohibits stress in the output (Prince and Smolensky, 1993). The analysis I propose does not hinge on employing the ANTI-FAITHFULNESS constraint, although the *STRESS implementation would affect constraint rankings in Section 4.5.2.

When ANTI^{MAXSTRESS} ($\neg Mx\acute{o}$) is operative, i.e. with dominant suffixes, it ranks above MAXSTRESS ($Mx\acute{o}$). For a cross-linguistic argument motivating the class of ANTI^{FAITHFULNESS} constraints and a formalization thereof, see Alderete (1999).

The ranking of ANTI^{MAXSTRESS} ($\neg Mx\acute{o}$) above MAXSTRESS ($Mx\acute{o}$) for level *o* dominant suffixes is captured in the revised grammar lattice below. For visual perspicuity, the ranking of $\neg Mx\acute{o}$ is not given in the lattice when the constraint ranks too low to be operative (i.e. below $Mx\acute{o}$ for *level o recessive* and *level 1*). This convention will be adopted in the coming revisions to the grammar lattice as well.

Grammar lattice, 3nd iteration.

Also observe that MAXSTRESS ($Mx\acute{o}$) is not operative at *level o dominant*. In every ranking at most one of MAXSTRESS ($Mx\acute{o}$) and ANTI^{MAXSTRESS} ($\neg Mx\acute{o}$) is operative. In the absence of stress, neither constraint is. In the presence of stress, it is either preserved (and $\neg Mx\acute{o}$ is inoperative) or deleted (and $Mx\acute{o}$ is inoperative).

The tableaux below demonstrate how dominance works with stressless and stressed stems. The former have no stress to delete (68'^a). The latter have their stress deleted by ANTI^{MAXSTRESS} ($\neg Mx\acute{o}$) (68'^c). In either case, penultimate stress is supplied at level 1.

To simplify presentation, violations of constraints peripheral to the discussion and of constraints ranking below operativeness in any given cophonology, e.g. ALIGNSTEM ($ó]$) and LxWD≈PRWD ($#ω\#$) at *level o*, MAXSTRESS ($Mx\acute{o}$) at *level o dominant*, and DEPSTRESS ($Dp\acute{o}$) at *level 1*, will not be explicitly spelled out.

		<i>level o dominant</i>

		‘speak-PASS’		

Given the definition of dominance as those suffixes which prioritize faithfulness to the stem over their own accentual specification, all the level 1 suffixes considered so far can be classified as recessive. Although they stress the last syllable of the stem, this is blocked by preexisting stress. The prestressing of a hypothetical level 1 dominant suffix would not be blocked by the stress on the stem: regular and irregular verbs alike would surface with stem-final stress.

This data pattern is in fact attested, which confirms the existence of level 1 dominant suffixes. The two level 1 dominant suffixes are the verbal diminutive *-kha* 'DMN' (71) and the prohibitive *-jama* 'PRHB' (72). Unlike recessives (70), level 1 dominant suffixes place stress on the syllable to their left with both lexically stressless (71-72a-b) and lexically stressed verbs (71-72c-d).

	STRESSLESS STEM		STRESSED STEM	
(70)	a. <i>panzá</i> -ya	b. <i>agathú</i> -ya	c. <i>áfa</i> -ya	d. <i>kúndase</i> -ya
	'hunt-IRR'	'count-IRR'	'speak-IRR'	'tell-IRR'
(71)	a. <i>panzá</i> - <i>kha</i>	b. <i>agathú</i> - <i>kha</i>	c. <i>afá</i> - <i>kha</i>	d. <i>kundasé</i> - <i>kha</i>
	'hunt-DMN'	'count-DMN'	'speak-DMN'	'tell-DMN'
(72)	a. <i>panzá</i> - <i>jama</i>	b. <i>agathú</i> - <i>jama</i>	c. <i>afá</i> - <i>jama</i>	d. <i>kundasé</i> - <i>jama</i>
	'hunt-PRHB'	'count-PRHB'	'speak-PRHB'	'tell-PRHB'

It will therefore be necessary to distinguish between two subcategories of level 1 suffixes. I will refer to the cophonologies which govern them as *level 1 recessive* or φ_1 and *level 1 dominant* or φ_1^X .

In formulating a hypothesis alternative to level 1 dominant suffixes, one could propose that *-kha* 'DMN' is a level 0 dominant suffix, deriving the penultimate stress of (71) in the same fashion as that of (68). This hypothesis is disconfirmed by negative forms, whose antepenultimate root-final stress (73) contrasts with the penultimate stress seen with level 0 dominant suffixes (69).

	UNIFORM PRESTRESSING			
(73)	a. <i>panzá</i> - <i>kha</i> - <i>mbi</i>	b. <i>agathú</i> - <i>kha</i> - <i>mbi</i>		
	'hunt-DMN-NEG'	'count-DMN-NEG'		
	c. <i>afá</i> - <i>kha</i> - <i>mbi</i>	d. <i>kundasé</i> - <i>kha</i> - <i>mbi</i>		
	'speak-DMN-NEG'	'tell-DMN-NEG'		

The dominance of the level 1 prohibitive *-jama* 'PRHB' is, on the other hand, further confirmed by the fact it enforces stem-final stress despite earlier-attaching level 1 suffixes, such as the plural subject *-'fa* 'PLS' (74). This is possible as preexisting stress is deleted.

	UNIFORM PRESTRESSING			
(74)	a. <i>panza</i> - <i>fá</i> - <i>jama</i>	b. <i>agathu</i> - <i>fá</i> - <i>jama</i>		
	'open-PLS-PRHB'	'count-PLS-PRHB'		
	c. <i>afa</i> - <i>fá</i> - <i>jama</i>	d. <i>kundase</i> - <i>fá</i> - <i>jama</i>		
	'speak-PLS-PRHB'	'tell-PLS-PRHB'		

Formally, the accentual properties of level 1 dominant suffixes can be captured by the same mechanism as the one just proposed for level 0 dominant suffixes. Ranking ANTI_{MAXSTRESS} ($\neg Mx\sigma$) above MAX_{STRESS} ($Mx\sigma$) ensures stress deletion and makes $Mx\sigma$ inoperative. The ranking of all other constraints is the same as that of *level 1 recessive*.

The tableaux below demonstrate how the proposed constraint rankings make correct predictions with level 1 dominant and recessive suffixes in either order.

When a level 1 dominant suffix attaches first, stress shifts to its left-adjacent syllable. A later attachment of a recessive suffix does not shift stress (73'c).

level 1 dominant					
(73') c.	[áfa]'	<i>kha</i> ₁ :	$\neg Mx\sigma$	$\# \omega \#$	$* \sigma \#$

‘speak–PLS–PRHB’

The template on the next page gives the complete morphophonology of verbal inflection, including information about phonological levels as well as recessiveness and dominance. Unlike level 0 and level 1, recessive and dominant suffixes are not linearly ordered.

The four cophonologies: *level 0 recessive*, *level 0 dominant*, *level 1 recessive*, and *level 1 dominant*, exhaust the language-internal morphological variation. Properties of each suffix lie at an intersection of its phonological level (zero or one) and its stem faithfulness (recessive or dominant). This systematicity can be captured in Cophonology Theory by associating each of *level 0*, *level 1*, *recessiveness*, and *dominance* with a partial ranking, and letting the each of the four cophonologies inherit from them appropriately. A multiple-inheritance hierarchy capturing this idea is given below.

Grammar lattice, 4th iteration.

Partial rankings associated with *level 0* and *recessive* cophonologies are not spelled out in the grammar lattice. MAXSTRESS ($Mxó$) ranks below ANTIMAXSTRESS ($\neg Mxó$) at *level 0*, and ALIGNSTEM ($\sigma]$) and LxWD≈PRWD ($\#ω\#$) rank below DEPSTRESS ($Dpó$) in *recessive* cophonologies, so they have no effect on how candidates are evaluated. Lastly, φ_1

Morphophonological template of verbal inflection, final iteration.

serves the doubly duty of being the cophonology of *level 1 recessive* suffixes as well as enforcing the requirements on the *prosodic word*.

The minimal six-tuple (1-6) given at the onset of [Chapter 4](#) demonstrates six different accentual patterns. The analysis so far accounts for four out the six members of the tuple (2-3, 5-6).

		a. <i>upathû ...-mbi</i>	b. <i>áfase ...-mbi</i>
		'pick ... -NEG'	'insult ... -NEG'
(2)	-'fa	'PLS'	<i>upathû</i> -'fa-mbi
(3)	- <i>ji</i>	'PRCM'	<i>upathû</i> - <i>jí</i> -mbi
(5)	-'kha	'DMN'	<i>upathû</i> -'kha-mbi
(6)	- <i>khu</i>	'RCPR'	<i>upathû</i> - <i>khú</i> -mbi

The plural subject -'fa 'PLS' is a level 1 recessive suffix. It places stress on the last syllable of the stem if no lexical stress is present (2a). If preexisting stress is present in stem stem, the plural subject -'fa 'PLS' preserves it (2b).

The precumulative -*ji* 'PRCM' is a level 0 recessive suffix. When attached to a regular stem without stress (3a), it allows stress to be decided by other mechanisms. Here, it is assigned by the negative -mbi 'NEG.' Since the negative -mbi 'NEG' is prestressing, stress surfaces on the precumulative -*ji* 'PRCM,' which immediately precedes it. The precumulative -*ji* 'PRCM' does not remove preexisting stress, so when it is attached to an irregular stem, stress stays the same as in the bare form (3b).

The verbal diminutive -'kha 'DMN' is a level 1 dominant suffix. It deletes the preexisting stress on the verb, if any, and stresses the syllable immediately to its left. Thus, the accent surfaces on the syllable preceding the diminutive -'kha 'DMN' whether or not lexical stress is present on the stem (5a-b).

The reciprocal -*khu* 'RCPR' is a level 0 dominant suffix. It deletes the stress of the stem and allows it to be decided by external means. Here again, it is assigned by the prestressing negative -mbi 'NEG.' As stem stress has been removed by -*khu* 'RCPR', it can be assigned to the syllable preceding -mbi 'NEG' regardless of the verbal class (6a-b).

In summary, a further distinction between *recessive* and *dominant* suffixes was made. Recessive suffixes are faithful to preexisting lexical stress at the cost of their own accentual specification. Dominant suffixes delete preexisting lexical stress (if any), which allows for their accentual properties to manifest equally with all verbs.

Cophonologies which inherit from the *dominant* node rank ANTI^{MAX STRESS} ($\neg Mx^0$) above MAX^{STRESS} (Mx^0), ensuring stress deletion. In

the *recessive cophonologies*, MAXSTRESS ($Mx\acute{o}$) is ranked above MAX STRESS ($Mx\acute{o}$), ensuring faithfulness to stress.

The recessive–dominant distinctions interacts with the two phonological levels proposed in Section 4.3, yielding four suffix types in total: *level 0 recessive*, *level 0 dominant*, *level 1 recessive*, and *level 1 dominant*.

Level 0 recessive suffixes count toward the prosodic word for the default penultimate assignment, but do not otherwise affect stress. Level 0 dominant suffixes delete the lexical stress of the domain to which they attach. Level 1 recessive suffixes place stress on the syllable immediately preceding them, unless lexical stress is present. Level 1 dominant place stress on the syllable immediately preceding them without exceptions.

4.5 GLOTTAL STRESS

Sections 4.3 and 4.4 dealt with the intralinguistic morphophonological variation of A'ingae—those properties of stress assignment which differ from suffix to suffix. The analysis I proposed distinguishes between four accentual types of suffixes, which is captured in Cophonology Theory by associating each accentual type with a separate cophonology—a phonological function particular to a subset of morphological constructions.

This morphology-oriented part of the analysis captured four stress patterns (2-3, 5-6) out of the six motivated by the initial minimal six-tuple (1-6). The other two (1, 4) will be captured by a phonology-orientated analysis where a unique prosodic role will be assigned to the glottal stop.

The contrast I am making between morphology- and phonology-oriented parts of the analysis corresponds to how general the phonological rules are. All the principles discussed so far have been crucially sensitive to the morphological composition of the word. The glottal stop-related stress mechanisms to be introduced in this section, on the other hand, are language-general, although they will interact with the morphological distinctions in important ways.

In the terms of Cophonology Theory's formalism, this distinction maps onto the geometry of the language's grammar lattice. The morphological analysis proposed four distinct cophonologies, which capture accentual properties of particular morphemes and correspond to the terminal nodes of the lattice. The phonological analysis will enrich only the *master ranking*, which captures the language's overarching phonology and corresponds to the root node of the lattice. For a discussion of grammar lattices, see Section 4.1.2.

[Section 4.5.1](#) summarizes previous literature on the A'ingae glottal stop, motivates weight distinctions, defines the proper foot, motivates the basic stress pattern induced by the glottal stop (referred to as *glottal stress*), formalizes an ALIGNMENT constraint capturing glottal stress (McCarthy and Prince, 1993), and motivates its ranking with respect to other constraints in the *master* ranking.

[Section 4.5.2](#) categorizes the ?-initial morphemes. The ?-initial suffixes which manifest glottal stress are shown to be (mostly dominant) level 0 suffixes. The ?-initial suffixes which do not manifest glottal stress are shown to be level 1 suffixes. The deletion of glottal stops in ?-initial suffixes is explained.

[Section 4.5.3](#) further motivates the analysis by pointing to two additional phenomena it explains at little to no additional theoretical cost: the lack of stressless verbs with glottal stops and the deletion of glottal stops in verbal stems induced by dominant suffixes. Lastly, a complication involving the simultaneous presence of the imperfective and an associated motion suffix is considered and resolved.

4.5.1 *glottal phonology*

Previous scholarship on the language does not generally recognize the relevance of glottal stops to stress assignment. F&H recognize that the segment is contrastive, as evidenced by minimal pairs (75-76), but do not assign it a prosodic role.

- | | | | | |
|------|------------------|-------------------|-----------------|-------------------|
| (75) | a. <i>chiga</i> | b. <i>an-mba</i> | c. <i>umba</i> | d. <i>tsa=ma</i> |
| | 'god' | 'eat-ss' | 'up' | 'that-ACC' |
| (76) | a. <i>chi'ga</i> | b. <i>an-'mba</i> | c. <i>u'mba</i> | d. <i>tsa-'ma</i> |
| | 'not want' | 'eat-N' | 'fill up' | 'that-FRST' |
| | "not want" | "yuca" | "fill up" | "but" |

Repetti-Ludlow et al. (2019) recognize several interesting properties of the glottal stop, which sets it apart from other segments. First, glottal stops are the only licensed coda. Furthermore, glottal stops are licensed almost exclusively in codas.⁶ Lastly, glottal stops are very often initial in functional morphemes. Indeed, most of the language's glottal minimal pairs are due to pairs of functional morphemes differing only in the presence of the glottal stop (75-76b, d).

⁶ The name of the language, *a'i=ngae* 'person=MANN,' is an obvious exception to this generalization. Repetti-Ludlow et al. (2019) analyze such cases as metathesis of the glottal stop out of a word-final position. Thus, the proposed underlying form of *a'i* 'person' is /ai?/, realized as [a?i]. The manner clitic =ngae 'MANN' attaches subsequent to the metathesis, yielding [a?i^rgæ].

M. B. Borman (1976) is a notable exception, observing that stress in words with glottal stops falls on the “penultimate syllable before the stop” (p. 3, translation mine). M. B. Borman (1976)’s observation is partially correct, as penultimate syllable before the glottal stop is stressed as long as the glottalized syllable is not a diphthong.

The prosodic significance of the glottal stop is most directly revealed in a comparison of stress induced by suffixes without glottal stops, such as *-ji* ‘PRCM’ (8), and with glottal stops, such as *-’je* ‘IMPV’ (9), on three different roots (7-9).

	V-FINAL STEM	V-FINAL STEM	VV-FINAL STEM
(7)	a. <i>fétha</i> ‘open’	b. <i>fúite</i> ‘help’	c. <i>fíndúi</i> ‘sweep’
(8)	a. <i>fethá-ji</i> ‘open-PRCM’	b. <i>fuité-ji</i> ‘help-PRCM’	c. <i>fundií-ji</i> ‘sweep-PRCM’
(9)	a. <i>fétha-’je</i> ‘open-IMPV’	b. <i>fúite-’je</i> ‘help-IMPV’	c. <i>fíndúi-’je</i> ‘sweep-IMPV’

All the three verbs are regular, so penultimate stress is observed on bare forms (7) as well as forms suffixed with the level o recessive *-ji* ‘PRCM’ (8). When suffixed with the ?-initial imperfective *-’je* ‘IMPV’, stress usually falls on the penultimate syllable before the glottal stop (9a-b), in accordance with M. B. Borman (1976). When the syllable left-adjacent to the glottal stops is a diphthong, however, stress is attracted to it (9c). M. B. Borman (1976)’s generalization can be refined: in words with glottal stops stress falls not on the penultimate syllable before the stop, but rather on the syllable with the penultimate mora before the glottal stop. This accentual pattern will be referred to as *glottal stress*.

To formulate an Optimality Theoretic account of the pattern, I will rephrase the generalization in terms of metrical structure. In particular, I will propose an language-particular principle which requires that glottal stops be located in the head foot, preferably at its right edge. The head foot is understood to be the foot which contains the stressed syllable. To comply with the requirement, metrical feet are constructed early in the derivation. They are right-aligned with the glottal stop as long as they are proper, but right-alignment is abandoned in avoidance of improper foot construction.

The proposed explanation hinges on (*fétha*) and (*fúite*) constituting proper feet (9'a-b), to the exclusion of *(*fíndúi*'), which is unattested (9'c*). Instead, the proper (*dúi’je*) is constructed and the glottal stop appears in a dispreferred foot-medial position (9'c).

	V-FINAL STEM	V-FINAL STEM	VV-FINAL STEM
(9') a.	<i>(fétha-')je</i> 'open-IMPV'	b. <i>(fúite-')je</i> 'help-IMPV'	c. * <i>(fúndúi-')je</i> <i>fún(dúi-')je</i> 'sweep-IMPV'

The observed foot structure is sensitive to diphthongs. This is commonly understood in terms of syllabic weight. In particular, I propose, A'ingae monophthongs count as light and diphthongs as heavy. The foot constructed in (9'a), therefore, has two light syllables (--) and the feet in (9'b-c) have a heavy and a light syllable (-). The foot avoided in (9'c*) has a light syllable followed by a heavy one (---).

The relevance of syllabic weight to the prosody of A'ingae has not been reported in previous scholarship, which either denies its existence or remains agnostic about it (M. B. Borman, 1962; F&H; Repetti-Ludlow et al., 2019). This oversight can be attributed to the language's very untypical profile.

First, diphthongs are the only heavy nuclei. There are no long vowels, and the language's only coda, the glottal stop, does not contribute weight in the typologically expected way. Since weight is associated with stress attraction, heavy glottal stops would predict stress attraction to the glottalized syllables across the board, not to the syllables which precede them (9a-b).

Second, diphthongs do not attract stress word-finally (3c). This can be seen as an additional metrical motivation for NONFINALITY (*ó#).

Third, diphthongs are rare in the language. Moreover, most diphthongs are root-final which, in conjunction with NONFINALITY (*ó#) and the preponderance of morphologically conditioned stress, makes their contribution to weight even harder to detect.

The shape of the A'ingae proper foot is captured by three uncontroversial Optimality Theoretic constraints: FOOTBINARITY, RHYTHMICTYPE: TROCHAIC, and STRESS→WEIGHTPRINCIPLE.

FOOTBINARITY ensures that feet comprise two units, be they syllables or morae (McCarthy and Prince, 1986; Prince, 1980; Prince and Smolensky, 1993). It is violated by light monosyllabic feet (--) and all feet larger than two heavy syllables (---).

FOOTBINARITY

Feet are binary under syllabic or moraic analysis.

RHYTHMICTYPE: TROCHAIC favors the left-prominent trochee over the right-prominent iamb (Hayes, 1985, 1995).

RHYTHMICTYPE: TROCHAIC, or TROCHEE

Feet are left-prominent.

STRESS→WEIGHTPRINCIPLE assigns violations for heavy syllables in unstressed positions (Prince, 1990). In a trochaic language, left foot branches are stressed (strong) and right foot branches are unstressed (weak). Thus, the constraint prevents heavy right branches.

STRESS→WEIGHTPRINCIPLE, or WSP

Heavy syllables are prosodic heads.

FOOTBINARITY eliminates all feet other than the mora-level binary (-), and the syllable-level binary (--) (--) (--) and (--) TROCHEE sets feet to be left-prominent and WSP eliminates those whose right branches are heavy. This leaves us with a set of three shapes: (-), (--) and (--) which comprise the language's proper foot.

Since FOOTBINARITY, TROCHEE, and WSP will largely remain unranked with respect to one another in the analysis to follow, I will subsume the three constraints under one FOOTSHAPE constraint violated whenever one of FOOTBINARITY, TROCHEE, or WSP is violated.

FOOTSHAPE, or ($\times\mu$)

Feet are trochees, whose right branches are monomoraic.

The requirement that glottal stops be located in the head foot can be captured with an ALIGNMENT constraint of McCarthy and Prince (1993)'s Generalized Alignment framework. In particular, the constraint states that every glottal stop coincides with the right edge of a prosodic head of the word.

ALIGN(?, R, WDHD, R), or HD?

Glottal stops are final in a prosodic head of the word.

The informal generalization stated that glottal stops must be located in the head foot. Since feet are strictly binary and glottal stops occur only in codas, this is tantamount being located in the coda of either of the two feet which comprise the head foot. ALIGNGLOTTAL (HD?) requires that every glottal stop be aligned with a word head. The head of the word is the head foot (i.e. the foot with the stressed syllable) but also, by transitivity of headship, the head syllable (i.e. the stressed syllable). Therefore, alignment with a word head is tantamount to head foot location. For the account which inspired this word-head-based formulation of ALIGNGLOTTAL (HD?), see Prince and Smolensky (1993)'s implementation of Latin extrametricality.

I will assume that one word head cannot count as both the head syllable and the head foot once, licensing two glottal stops. In other words, ($\delta'\sigma'$) is not a legal structure. This effectively enforces that there be at most one glottal stop per word. I will invoke this assumption by the end of the this chapter in accounting for some empirical intricacies.

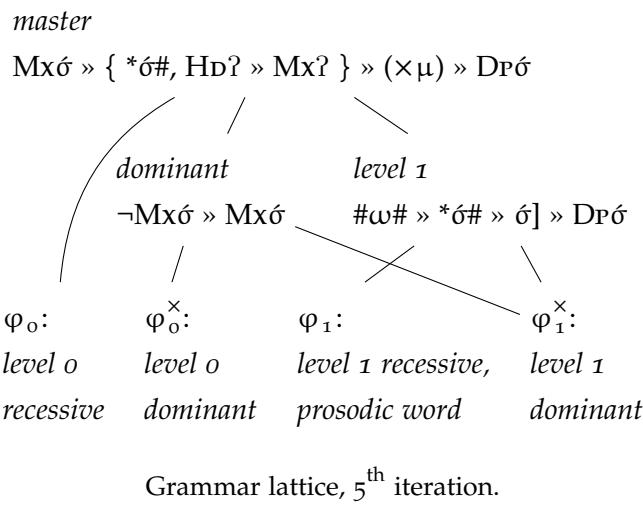

ALIGNGLOTTAL (HD?) is a surface-true generalization, which means it is high-ranked. In the absence of a word head right-aligned with the

glottal stop in the input, there are two in-principle ways of satisfying the constraint: glottal stop deletion and construction of metrical structure. Empirically, the latter is attested (9^l), which means that faithfulness to glottal stops ranks above DEPSTRESS (Dp̄). Faithfulness to glottal stops is captured with a MAXIMALITY constraint (McCarthy and Prince, 1995).

MAXIMALITY(?), or Mx?

Glottal stops are not deleted.

The ranking details discussed in the preceding paragraphs are hold true of the language as a whole, i.e. they are not particularized to cophonologies associated with specific suffixes. They are therefore captured in the *master* ranking, from which all other rankings inherit.⁷

The ranking as discussed up to this point correctly accounts for stress with heavy-final stems (9["]), but it is insufficient to pick a unique candidate when light-final stems are considered (9^{"*a-b}). The constraint ALIGNSTEM (ó]) aligns the glottal stop with the right edge of a head foot syllable, correctly eliminating candidates (9^{"*a-b.i}). Yet, there are two syllables in the head foot, and nothing as of now discriminates between (9^{"*a-b.ii}) and (9^{"*a-b.iii}).⁸

⁷ In the previous iteration of the grammar lattice, ALIGNSTEM (ó]) was ranked above DEPSTRESS (Dp̄), which allowed for supplying stem-final stress with level 1 suffixes and penultimate stress by prosodic default. With the introduction of FOOTSHAPE (xμ), ALIGNSTEM (ó]) is now ranked above it. This is necessary to account for penultimate stress in heavy-final words, e.g. *fíndúi* 'sweep' (7c), where a non-proper light-heavy foot (--) must presumably be created.

⁸ In contrast to what the tableaux intimate, the ranking of FOOTSHAPE (xμ) over ALIGN GLOTTAL (Hd?) would also yield the correct output. The chosen ranking of ALIGN GLOTTAL (Hd?) above FOOTSHAPE (xμ) will be motivated on page 79.

		‘sweep-IMPV’	

An ALIGNMENT constraint will be used to overcome this impasse. In particular, the constraint will require that the left edge of the prosodic word coincide with a foot. ALIGNWORD (#φ) will be further motivated in [Section 4.6](#), where it will be shown it is independently needed to account for secondary stress.

ALIGN(PrWD, L, Ft, L), or #φ

A foot is word-initial.

ALIGNWORD (#φ) is dominated by DEPSTRESS (DPጀ), which means that it does not construct new metrical feet by itself. Yet—the constraint does, through the emergence of the unmarked, push for left-aligned feet when feet are being constructed to comply with higher-ranked constraints (9"^{a-b}).

4.5.2 glottal morphology

The preceding subsection showed that in the absence of a word head right-aligned with the glottal stop in the input, ALIGNGLOTTAL (Hd?) is satisfied by constructing new metrical structure. This is captured by raking MAXGLOTTAL (Mx?) above DEPSTRESS (DPṄ). Another question arises in the case when a metrical foot is present in the input, but it is not aligned with the glottal stop. Due to culminativity, there cannot be two primary stresses in a word. The two conceivable outcomes therefore are: the erasure of preexisting metrical structure (and the construction of a new adequately-aligned metrical foot) and the deletion of the glottal stop.

The actual outcome is, conceivably, morpheme dependent. All the ?-initial level o suffixes listed in the template of verbal inflections, i.e. the imperfective –*je* 'IMPV,' the semelfactive –*ñakha* 'SMFC,' the venitive –*ngi* 'VEN,' and the andative –*nga* 'AND,' stress the syllable containing the penultimate mora before the glottal stop with all stems, including lexically stressed verbs.⁹ This furnishes a reason to

⁹ The level o dominant semelfactive –*ñakha* 'SMFC,' venitive –*ngi* 'VEN,' and andative –*nga* 'AND' are transcribed by F&H without glottal stops. This is plausibly explained as a morphophonology-phonetics interaction. Since most verbs end in light syllables and all three of –*je* 'IMPV,' –*ñakha* 'SMFC,' and –*ngi* 'VEN' place stress on the syllable with the penultimate mora before the glottal stop, the three suffixes are almost always realized with creaky voice and almost never with a full glottal closure (for a discussion of the phonetics of glottal stops, see Section 2.5). Thus, when facts about stress are neglected, it is easy to miss the underlying glottal stops.

classify them as dominant suffixes with the high-ranking ANTI^{MAX} STRESS ($\neg Mx\sigma$) ensuring deletion of metrical structure.

Lexically stressed verbs arguably come with a lexically specified left-aligned foot (details of the implementation are immaterial to the point at hand). Due to the high ranking of both ANTI^{MAX}STRESS ($\neg Mx\sigma$) and ALIGNGLOTTAL (HD?), that stress is deleted and a new foot right-aligned with the glottal stop is constructed (77).

level o dominant					
(77)	$[(\underline{\alpha}f\underline{a})se]'$	$je_0^\times:$	$\neg Mx\sigma \gg HD? \gg Mx? \gg DP\sigma \gg \#φ$		
i.	<i>afaseje</i>		*!	_____	
ii.	<i>afase'je</i>		*!	_____	
iii.	<i>(<u>af</u>)seje</i>	*!		_____	
iv.	<i>a(<u>fá</u>se')je</i>		*	*	
v.	<i>afa(sé)je</i>		*	**!	

'insult-IMPV'

It is not clear if there are any level o recessive ?-initial suffixes. A possible candidate is the nominalizing subordinator $-'chu$ 'SBRD,' which in some idiolects behaves as one. It stresses the syllable containing the second mora to the left of the glottal stop (78a-b) unless another stress is lexically present (78c). This can be modeled by high-ranking MAXSTRESS ($Mx\sigma$), which furnishes a reason to class $-'chu$ 'SBRD' with level o recessive suffixes.¹⁰

	V-FINAL STEM	VV-FINAL STEM	STRESSED STEM
(78)	a. <i>pánza-'chu</i> 'hunt-SBRD'	b. <i>fíndúi-'chu</i> 'sweep-SBRD'	c. <i>áfase-chu</i> 'insult-SBRD'

The level 1 recessive apprehensional $-sa'ne$ 'APPR' is also transcribed by F&H without the glottal stop. Due its morpheme-internal position, the glottal stop in $-sa'ne$ 'APPR' is also at best final in the posttonic syllable—in which case it is realized with creaky voice—or further away from stress still—in which case it is not realized at all. Thus, similar reasoning applies.

For a transcription of the imperfective $-je$ 'IMPV,' the semelfactive $-\tilde{n}akha$ 'SMFC,' the venitive $-\tilde{n}gi$ 'VEN,' the andative $-\tilde{n}ga$ 'AND,' and the apprehensional $-sa'ne$ 'APPR' with glottal stops, corroborating my analysis, see M. B. Borman (1976).

¹⁰ Classing the nominalizing subordinator $-'chu$ 'SBRD' with level o recessive suffixes poses a challenge to the previously established strict phonological layering of the A'ingae verb, as $-'chu$ 'SBRD' can attach to verbs inflected with level 1 suffixes as well. Yet, since there is considerable variation in the realization of stress with $-'chu$ 'SBRD,' there are many lexicalized $-'chu$ 'SBRD'-final nouns, and the subordinate clauses it forms are nominal rather than verbal, testifying to its derivational properties and at the same time excluding it from the template of verbal inflections altogether, it is ultimately not obvious what light $-'chu$ 'SBRD' sheds on the hypothesis of string phonological layering in A'ingae.

The high-ranking ALIGNGLOTTAL ($Hd?$) supplies stress when no lexical stress is present on the stem (78'*a-b*).

level o recessive					
(78')	a.	[panza]’chu _o :	Mx᷑ »	Hd? »	Mx? » Dp᷑ » #φ
	i.	panzachu		*!	_____
	ii.	panza’chu		*!	_____
	III	iii. (pánza’)chu		*	
	iv.	pan(zá’chu)		*	*!
‘hunt–SBRD’					

level o recessive					
(78')	b.	[fündüi]’chu _o :	Mx᷑ »	Hd? »	Mx? » Dp᷑ » #φ
	i.	fündüichu		*!	_____
	ii.	fündüi’chu		*!	_____
	III	iii. (fúndüi’)chu		*	
	iv.	fün(dúi’)chu		*	*!
‘sweep–SBRD’					

When lexical stress is present, the even-higher-ranking MAXSTRESS ($Mx᷑$) prevents its deletion (78'*c*).

level o recessive					
(78')	c.	[(áfa)se]’chu _o :	Mx᷑ »	Hd? »	Mx? » Dp᷑ » #φ
	III	i. (áfa)sechu		*	_____
	ii.	(áfa)se’chu		*!	_____
	III	iii. a(fáse’)chu	*!		_____
‘insult–SBRD’					

As seen above, the winner still avoids the violation of ALIGNGLOTTAL ($Hd?$). Instead, the lower-ranking MAXGLOTTAL ($Mx?$) is violated in the output. This interaction of $Mx᷑$, $Hd?$, and $Mx?$ explains the glottal stop erasure phenomena first brought up with (1-2b).

		a. <i>upathû ...-mbi</i> 'pick ...-NEG'	b. <i>áfase ...-mbi</i> 'insult ...-NEG'
(1)	-'chu	'SBRD'	<i>upáthû-</i> 'chu-mbi <i>áfase-chu-mbi</i>
(2)	-'fa	'PLS'	<i>upathû-</i> 'fa-mbi <i>áfase-fa-mbi</i>
(3)	-'ji	'PRCM'	<i>upathû-</i> jí-mbi <i>áfase-ji-mbi</i>
(4)	-'je	'IMPV'	<i>upáthû-</i> 'je-mbi <i>afáse-'je-mbi</i>
(5)	-'kha	'DMN'	<i>upathiú-</i> 'kha-mbi <i>afasé-'kha-mbi</i>
(6)	-khu	'RCPR'	<i>upathû-</i> khu-mbi <i>afase-khu-mbi</i>

Hereby, the last two verb pairs of the minimal six-tuple (1-6) have been accounted for. The accentual difference between the subordinating -'chu 'SBRD' (1) and the precumulative -'ji 'PRCM' (3) and between the imperfective -'je 'IMPV' (4) and the reciprocal -khu 'RCPR' (6) is explained in terms of phonological properties of the glottal stop which are not particular to the suffixes themselves. Morphophonology-wise, both -'chu 'SBRD' (1) and -'ji 'PRCM' (3) are level o recessive. Both -'je 'IMPV' (4) and -khu 'RCPR' (6) are level o dominant.

Morpheme-initial glottal stops do not result in a comparable split among level 1 suffixes. This is because at level 1, stress is assigned stem-finally. Stem-final stress induced by level 1 suffixes does not incur ALIGNGLOTTAL (Hd?) violations, as the formulation of ALIGN GLOTTAL (Hd?) is consistent with syllable-wise alignment, but the characteristic pattern of stress on the syllable containing the mora penultimate before the glottal stop is absent (79).

<i>level 1 recessive</i>						
(79)	[panza]'	fa _{1:}	Mx᷑ »	HD? »	Mx᷑, ᶒ] »	Dp᷑

‘insult–PLS’

4.5.3 additional purchases

ALIGNGLOTTAL (Hd?) has so far been motivated through an account of the second-mora-west-of-the-glottal-stop stress with ?-initial suffixes, and the occasional glottal stop deletion at morpheme boundaries. ALIGNGLOTTAL (Hd?) is, however, a generally operative principle in the grammar of A’ingae. Two additional phenomena it explains at little to no additional theoretical cost are the lack of stressless glottal verbs and glottal stop deletion induced by dominant suffixes.

First, there are no verbal roots with glottal stops, but without stress. This is to say, while glottalless verbs split between lexically stressless (81–83a) and stressed (81–83b), all the verbs with glottal stops pattern with the lexically stressed (irregular) verbs (81–83c). There are no stressless verbs with glottal stops.¹¹

	STRESSLESS	STRESSED	GLOTTAL
(81)	a. <i>panza</i> ‘hunt’	b. <i>áfa</i> ‘speak’	c. <i>sé’je</i> ‘cure’
(82)	a. <i>fetha</i> ‘open’	b. <i>páña</i> ‘hear’	c. <i>fi’thi</i> ‘kill’
(83)	a. <i>upathu</i> ‘pick’	b. <i>áfase</i> ‘offend’	c. <i>ákhe’pa</i> ‘forget’

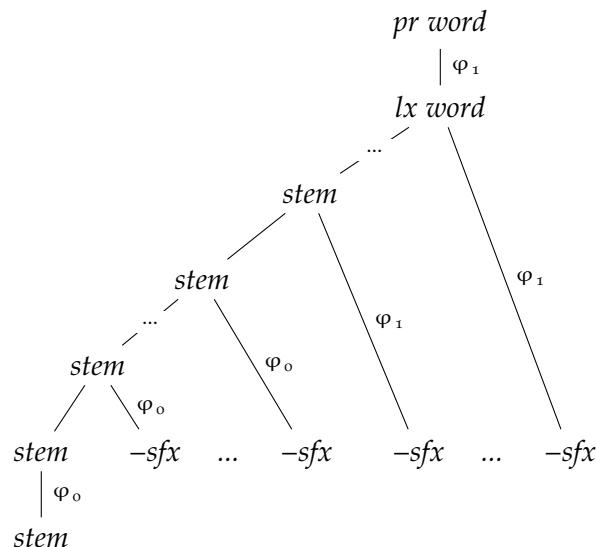

¹¹ Glottal stops are not allowed in a word-final position (for a brief discussion of a related phenomenon of glottal metathesis, see the footnote on page 67). Thus, all bisyllabic glottalized roots have the form [(᷑᷑᷑)]. Curiously, all trisyllabic glottalized roots have the form [(᷑᷑᷑᷑᷑)]. No morphologically simplex verbs of the form [(᷑᷑᷑᷑᷑᷑)] have been attested. This is to say, in trisyllabic verbs, always the penultimate syllable is closed by the glottal stop; never the antepenultimate. One might want to relate this to the glottal stops’ preference for the head-final position, heretofore formalized with ALIGNWORD (#φ), but strictly speaking, nothing in the analysis as of now predicts this. For a possible extension of the current proposal, capturing the distribution of glottal stops in roots, see Section 4.7.

The asymmetry is made fully explicit in the table below, which categorizes verbs along the dimensions of stressedness/stresslessness and the presence of glottal stops.

	-GLOTTAL STOP	+GLOTTAL STOP
-STRESS	attested (81-83a)	unattested
+STRESS	attested (81-83b)	attested (81-83c)

Verbs by stress and glottal stops.

Although all verbs with glottal stops pattern with the irregulars, their stress will not be lexically listed. Instead, their initial stress is accounted for by proposing that verbal roots undergo level 0 cophonology. Thus, the morphophonological structure of the A'ingae verb is revised once again, to include a unary application of level 0 cophonology before suffixation.

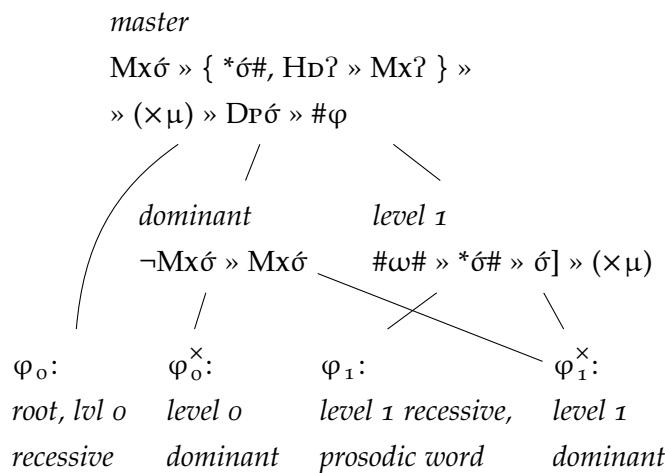

Word tree, phonological layering, 2nd iteration.

In level 0 cophonology, stressless verbs remain stressless (81'¹a), lexically stressed verbs remain stressed (82'¹a), and ALIGNGLOTTAL (Hd?) supplies stress to glottal verbs (83'¹a), thus deriving the asymmetry of the table above.

		root
(81')	a.	[panza] _{o:} Mxጀ » Hd? » Mx? » DPጀ
	i.	panza
	ii.	(pánza) *
		'hunt'

root					
(82 ¹)	a.	[áfa] _{o:}	Mx᷑ »	HD? »	Mx? » DP᷑
	i.	<i>afa</i>	*!		
	ii.	(áfa)			
'speak'					
root					
(83 ¹)	a.	[se'je] _{o:}	Mx᷑ »	HD? »	Mx? » DP᷑
	i.	<i>seje</i>		*!	
	ii.	<i>se'je</i>			
	iii.	(<u>sé</u> 'je)			*
'cure'					

Thus, φ_0 plays a double role: it is the cophonology of *level 0 recessive* suffixes, as well as the *root* cophonology of verbal stems before affixation. (Analogously, φ_1 is the cophonology of *level 1 recessive* suffixes as well as the *prosodic word* cophonology assigning penultimate stress to lexically stressless words.) The grammar lattice below captures all the ranking details discussed so far.

Grammar lattice, 6th iteration.

ALIGNGLOTTAL ($Hd?$) is ranked above **FOOTSHAPE** ($\times \mu$). The motivation for this ranking comes from disyllabic heavy-final verbs with a glottal stop where the satisfaction of **ALIGNGLOTTAL** ($Hd?$) requires the construction of an improper foot (84).

root

(84)	$[am'bian]_o:$	$\text{HD?} \gg \text{Mx?} \gg (\times \mu)$	
	i. <i>ambian</i>	*!	_____
	ii. <i>am'bian</i>	*!	_____
	iii. <i>(ám'bian)</i>	*	

'have'

Second, ALIGNGLOTTAL (HD?) necessitates that stress deletion triggered by dominant suffixes be accompanied by glottal stop deletion.

level o dominant

(85)	$[(sé'je)]ye_o^{\times}:$	$\neg\text{Mxó} \gg \text{HD?} \gg \text{Mx?} \gg \text{Dpó}$	
	i. <i>sejeye</i>	*	_____
	ii. <i>se'jeye</i>	*!	_____
	iii. <i>(sé'je)ye</i>	*!	_____

'cure-PASS'

In a passive construction, the winning (83'a.iii) becomes an input to (85). Candidate (85ii) complies with MAXSTRESS (Mxó), but violates ALIGNGLOTTAL (HD?). Thus, candidate (85i), which violates the lower-ranking MAXGLOTTAL (Mx?), wins.

Glottal stop deletion takes place even if stress ends up surfacing on the same syllable as the syllable stressed in the input. This can be the output of a morphological construction where the input suffix itself is ?-initial (86).

level o dominant

(86)	$[(sé'je)]'je_o^{\times}:$	$\neg\text{Mxó} \gg \text{HD?} \gg \text{Mx?} \gg \text{Dpó}$	
	i. <i>seje'je</i>	*!	_____
	ii. <i>se'je'je</i>	*!*	_____
	iii. <i>(séje')je</i>	*	_____
	iv. <i>(sé'je')je</i>	*!	_____

'cure-IMPV'

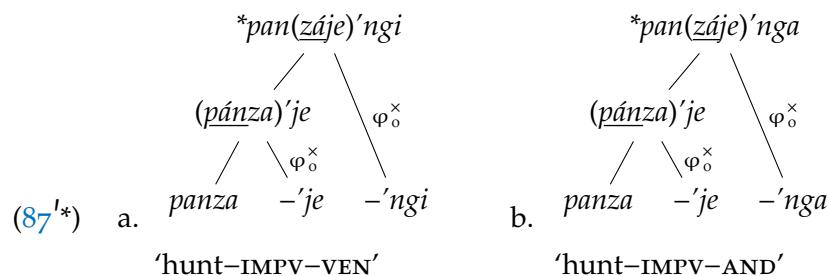

That the same syllable is stressed in the input and the output is, in some sense, a coincidence. The input stress is a consequence of the glottal stop in the stem, whereas the output stress is a consequence of the suffix's glottal stop and the deletion of input stress, accompanied by the deletion of the stem's glottal stop. For the satisfaction of

ANTI MAX STRESS ($\neg Mx\sigma$), the output stress must be considered as formally different from the input stress. As the input stress is deleted, the glottal stop is banished with it.

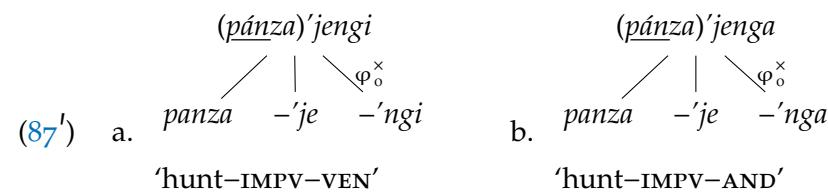

Finally, a minor complication to the picture must be considered. The imperfective *-je* 'IMPV' can be succeeded by either of the two associated motion suffixes, the venitive *-ngi* 'VEN' or the andative *-nga* 'AND.' Stress is on the penultimate syllable before *-je* 'IMPV' (87).

STEM-PENULTIMATE STRESS

Yet, since both the imperfective *-je* 'IMPV' and the andative suffixes are dominant and ?-initial, the null hypothesis predicts Hd?-governed stress assignment in the imperfective construction, followed by stress deletion and stress reassignment in an associated motion construction (87^{1*}). The current analysis, as it stands, seems to be making wrong predictions.

The conflict between the data and the analysis is resolved by attaching the imperfective and the associated motion suffixes to the verb in a ternary branching structure (87').¹² For ternary branching to be possible, the cophonologies of individual suffixes must match (Or-gun, 1996). This prerequisite is satisfied, as *-je* 'IMPV,' *-ngi* 'VEN,' and *-nga* 'AND' are all level o dominant.

¹² An additional motivation for attaching the imperfective and the associated motion suffixes in a ternary branching structure comes from co-occurrence restrictions. The imperfective *-je* 'IMPV' is the only aspectual suffix which can occur with either *-ngi* 'VEN' or *-nga* 'AND,' which testifies to their closer morphological relation. For a cross-linguistic motivation of n-ary branching, see Orgun (1996).

The intermediate (*pánza*)'je 'hunt–IMPV' is present when the branching is binary (87["]), but not when it is ternary (87[']). In the flat structure, only *panza* 'hunt' is the stem, which predicts correct output (87["]a.iii). Candidate (87["]a.vi) is ruled out by ALIGNSTEM (ó]) because one word head does not count as right-aligned with two glottal stops. For an introduction of this idea, see page 70.

level o dominant					
(87 ["])	a.	[<i>panza</i>]'je'ngi ^x	Hd? »	Mx? »	Dpó » #φ
	i.	<i>panzajengi</i>		**!	_____
	ii.	<i>panza'jengi</i>	*!		_____
☛	iii.	(<i>pánza</i>)'jengi		*	*
	iv.	(<i>pánza</i>)'je'ngi	*!		_____
	v.	<i>pan(záje')ngi</i>		*	*
	vi.	<i>pan(zá'je')ngi</i>	*!		**!

'hunt–IMPV–VEN'

In summary, syllabic weight has been recognized to play a role in the stress assignment. Glottal stops have been shown to induce stress on the syllable containing the second mora to the left of the glottal stop.

The accentual pattern associated with the glottal stops has been captured with the ALIGNGLOTTAL (Hd?) constraint, which requires that glottal stops be final in a prosodic head of the word and a lower ranking ALIGNWORD (#φ), which pushes for word-initial feet.

ALIGNGLOTTAL (Hd?) explains why level o suffixes exhibit two types of accentual behavior—level o suffixes without initial glottal stops do not contribute stress, while level o suffixes with initial glottal stops allow for glottal stress to manifest. A similar glottal-based split is not observed among level 1 suffixes, as their prestressing obscures the operation of ALIGNGLOTTAL (Hd?).

ALIGNGLOTTAL (Hd?) explains A'ingae glottal deletion phenomena. The obedience to ALIGNGLOTTAL (Hd?) ranks higher than faithfulness to glottal stops in the *master* ranking. When *recessive* suffixes are at play, ALIGNGLOTTAL (Hd?) is in addition ranked below faithfulness to stress. As a consequence, the conflict between extant stress and ALIGNGLOTTAL (Hd?) is resolved by removing the glottal stop.

Lastly, ALIGNGLOTTAL (Hd?) explains the absence of a class of otherwise expected verbal roots, specifically: stressless roots with glottal stops. This is achieved by having the *level o* cophonology apply to roots in a unary construction before affixation.

4.6 SECONDARY STRESS

Secondary stress is predictable given primary stress. No morphophonological conditioning has been observed. Therefore, secondary stress can be considered purely phonological. It is marked with the grave accent and an underline.

If primary stress is abstracted away, and weight distinctions momentarily neglected, secondary stress is observed to fall on the first syllable of the word and even syllables counting from the right. It does not fall on two adjacent syllables. Assuming trochaic parsing (see [Section 4.5.1](#)), the pattern can be schematized as follows: #(ðσ)σ(ðσ)(ðσ)#. This pattern of stress, dubbed *initial dactyl effect* by Prince (1983), has been observed in Garawa, English, Polish, Spanish, and others (Furby, 1974; Hayes, 1980, 1995; Prince, 1983; others).

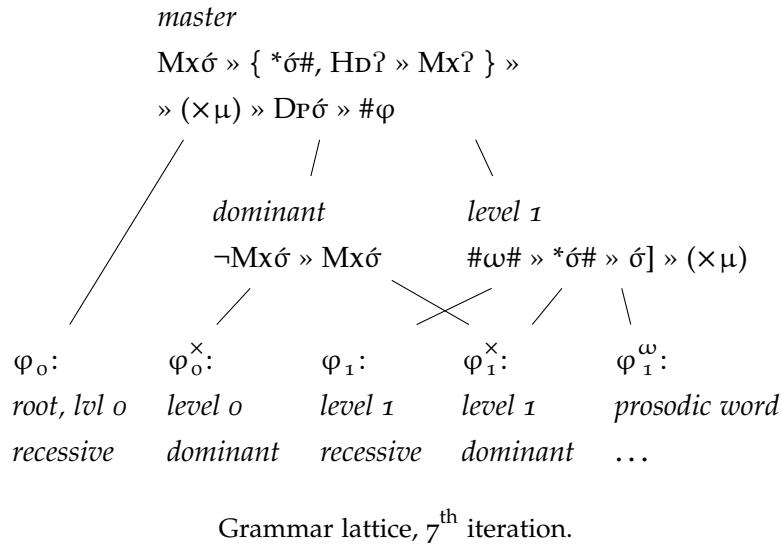

First, consider secondary stress as assigned to even syllables counting from the right edge the word. As the verb becomes progressively more complex, the primary morphologically conditioned (here, lexically listed) stress can remain fixed (88a-f), but secondary stress re-aligns with respect to the right edge (88c-f). The yields a pattern where verbs with an even number of syllable are fully parsed (88a, c, e), but verbs with an odd number of syllables have an unfooted syllable following the head foot (88b, d, f).

	EVEN SYLLABLES	ODD SYLLABLES
(88)	a. (<u>ðfa</u>)	b. (<u>ðfa</u>)-ji
	c. (<u>ðfa</u>)-(<u>jì</u> -ya)	d. (<u>ðfa</u>)-ji-(<u>yà</u> -mbi)
	e. (<u>ðfa</u>)-(<u>jì</u> -ya)-(<u>mbì</u> -ti)	f. (<u>ðfa</u>)-ji-(<u>yà</u> -mbi)-(<u>tì</u> -ki)
	f. 'speak-PRCM-IRR-NEG-INT-2' "will you not be about to speak?"	

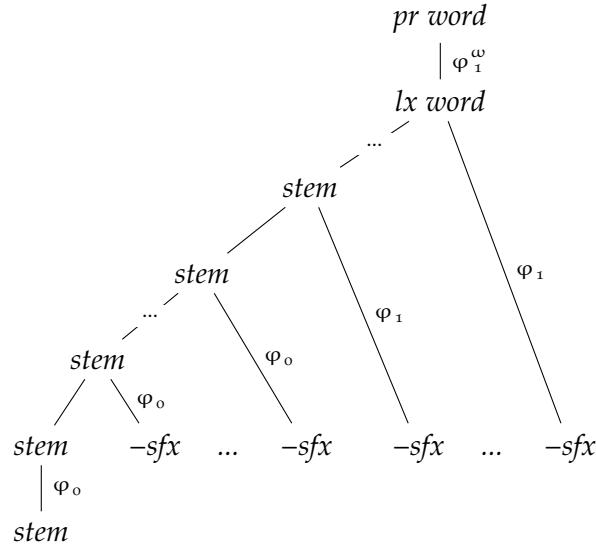

Up to now, the late-attaching level 1 suffixes and the penultimate stress supplied to prosodic words by default have been associated with *level 1*. Since both the prestressing of the late-attaching suffixes and the penultimate prosodic default were captured with one constraint ranking, there was no need to posit separate cophonologies.

Now, secondary stress, unlike primary, is purely phonological. It is assigned only once at the level of the prosodic word, which calls for a revision of this picture. Since the secondary stress is assigned only at the level of the prosodic word, a separate *prosodic word* cophonology will be introduced. I will alternatively refer to it as φ_1^ω . The omega ω symbolizes the prosodic word. The parsimony of using one constraint ranking to account for the prestressing of level 1 suffixes and the prosodic penultimate default will be retained as all cophonologies

associated with level 1 will inherit from the *level 1* node. A skeletal grammar lattice illustrating this is given below.

The morphophonological structure of the A'ingae verb will now be revised for the last time, reflecting the newly made distinction between the cophonologies φ_1 and φ_1^ω .

Word tree, phonological layering, final iteration.

All syllables are parsed by feet. This requirement, known in the metrical theories of stress as the exhaustivity of foot parsing, is captured by PARSESYLLABLES (Halle and Vergnaud, 1987; Hayes, 1987; Liberman and Prince, 1977; McCarthy and Prince, 1993; Prince, 1980; others).

PARSESYLLABLES, or $*\langle \sigma \rangle$

All syllables are parsed by feet.

`PARSESYLL *⟨σ⟩` incurs a violation for each unparsed syllable. Foot `SHAPE (xμ)` dominates `PARSESYLL *⟨σ⟩`, ensuring that footing is binary. Binary footing, in turn, entails that `PARSESYLL *⟨σ⟩` always incurs at least one violation in words with an odd number of light syllables (88b, d, f).

Whether foot-parsing takes place depends on the relative ranking of `PARSESYLL *⟨σ⟩` and a `DEPENDENCE` constraint preventing metrical structure epenthesis. At *lexical* levels, secondary stress is not assigned, so `DEPENDENCE(STRUCTURE)` dominates `PARSESYLL *⟨σ⟩`. At the *prosodic word* level, secondary stress is assigned, so the ranking of these constraints is reversed.

`DEPENDENCE(STRUCTURE)`, or $D_P\varphi$
Metrical structure is not epenthesized.

`DEPSTRUCT (D_P\varphi)` subsumes and replaces the previously formulated temporary constraint `DEPSTRESS (D_Pó)`, since both primary and secondary stress are understood to be properties of metrical structure.

Observe that since secondary stress is assigned only once at the level of the prosodic word, `PARSESYLL *⟨σ⟩` and `DEPSTRUCT (D_P\varphi)` are perfectly antagonistic: the former assigns violations for syllables outside of metrical structure whereas the latter for construction of new metrical structure. Thus, the lower ranking of the two constraints is always inoperative.

The directionality of parsing is captured by a gradient `ALIGNMENT` constraint, which states that every foot coincides with the right edge of the prosodic word (McCarthy and Prince, 1993). It incurs a violation for each foot and each syllable away from the right word edge.

`ALIGN(Ft, R, PrWd, R)`, or $\varphi\varphi\#$
Feet are word-final.

Since foot parsing is exhaustive, `ALIGNFEET (φφ#)` is ranked below `PARSESYLL *⟨σ⟩`.¹³ Given that polysyllabic words have multiple feet and only one right prosodic edge, even the winning candidate will often incur plenty of `ALIGNFEET (φφ#)` violations. In the tableaux below, violations of `PARSESYLL *⟨σ⟩` will be counted for each foot separately and represented with numerals.

¹³ For a factorial typology of stress, see McCarthy and Prince (1993).

prosodic word				
(88')	f.	$[(\underline{\alpha}fa)jiyambitiki]_1^\omega :$	$(\times\mu) \gg *(\sigma) \gg \varphi\varphi\#$	
	i.	$(\underline{\alpha}fa)jiyambi(\underline{t}iki)$	$**!*$	—
	ii.	$(\underline{\alpha}fa)(\underline{j}iya)(\underline{m}biti)ki$	*	5, 3, 1!
	iii.	$(\underline{\alpha}fa)(\underline{j}iya)mbi(\underline{t}iki)$	*	5, 3!, 0
	iv.	$\blacksquare (\underline{\alpha}fa)ji(y\underline{a}mbi)(\underline{t}iki)$	*	5, 2, 0
	v.	$(\underline{\alpha}fa)(\underline{j}i)(y\underline{a}mbi)(\underline{t}iki)$	*!	—————

'speak–PRCM–IRR–NEG–INT–2'

Now consider the word-initial secondary stress. When at least three syllables precede the word head, a deviation from right-aligned secondary stress is observed (90a-b). Secondary stress is in those cases word initial regardless of whether the base form is lexically stressless (89a) or stressed (89b).

	STRESSLESS STEM	STRESSED STEM
(89)	a. $ka(\underline{s}ára)$ 'marry'	b. $(\underline{\alpha}fa)se$ 'insult'
(90)	a. $(\underline{k}ása)ra-(\underline{k}huí-'fa)$ 'marry–RCPR–PLS'	b. $(\underline{\alpha}fa)se-(\underline{k}huí-'fa)$ 'insult–RCPR–PLS'

The above pattern is captured by ranking ALIGNWORD (#φ) (introduced in [Section 4.5.1](#)) above ALIGNFEET (φφ#).

ALIGN(PrWD, L, Ft, L), or #φ

A foot is word-initial.

ALIGNWORD (#φ) states that the left edge of the prosodic word coincides with a foot. ALIGNFEET (φφ#) states that every foot coincides with the right edge of the prosodic word. Formally, the difference between the two constraints lies in the order of their arguments. The first argument is quantified over universally, while the second argument—existentially. Thus, ALIGNFEET (φφ#) demands of every foot that it be next to a right word edge, while ALIGNWORD (#φ)—of every left word edge that it be next to a foot. In other words, ALIGNWORD (#φ) is content with just one foot by the left word edge, while ALIGNFEET (φφ#) pushes all the feet to the right.

The interaction of ALIGNWORD (#φ) and ALIGNFEET (φφ#) derives a stress system in which one foot is aligned with the left edge of the word while all others are pushed rightward: #(ðσ)σ(ðσ)(ðσ)#. For an identical account of the Garawa stress pattern and for details on the Generalized Alignment formalism, see McCarthy and Prince ([1993](#)).

prosodic word				
(90')	a.	[kasara(<u>khú</u> -'fa)] ₁ ^ω :	*⟨σ⟩ » #φ » φφ#	
	i.	kasara(<u>khú</u> -'fa)	**!*	_____
	II	ii. (<u>kàsa</u>)ra(<u>khú</u> -'fa)	*	3, o
	iii.	ka(sàra)(<u>khú</u> -'fa)	*	*!

'marry–RCPR–PLS'

Finally, a word on weight sensitivity in secondary stress. Diphthongs are rare in the language, and almost all are found at the right edge of bare verbs, where primary stress is most often assigned by morphological means. In addition, almost all functional morphemes consist of light syllables.¹⁴ Thus, it is difficult to discern the exact role of syllabic weight in secondary stress assignment.

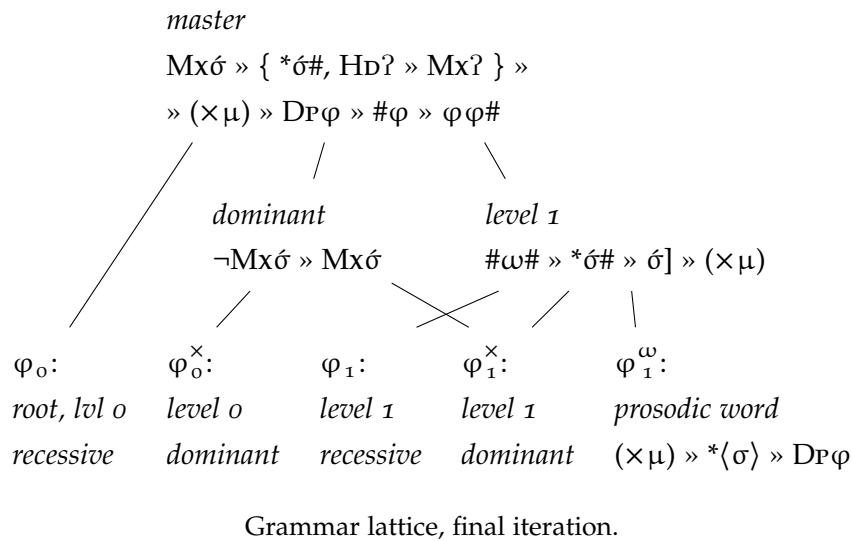

On the whole, the predictions made by ranking FOOTSHAPE ($\times\mu$) above ALIGNWORD (#φ) and ALIGNFEET (φφ#) have been corroborated. Weight sensitivity shows that only proper feet are constructed, which can be discerned—for example—in the assignment of secondary stress to the second syllable of the word when heavy (91).

prosodic word				
(91)		[fûndûi(yémbi)] ₁ ^ω :	($\times\mu$) » *⟨σ⟩	
	i.	fûndûi(yémbi)	**!	
	II	ii. fûn(<u>dûi</u>)(yémbi)	*	
	iii.	(<u>fûndûi</u>)(yémbi)	*!	_____
				'sweep–PASS–NEG'

Finally, the complete grammar lattice is given, with all the constraint rankings necessary to account for the discussed phenomena.

In summary, A'ingae secondary stress is purely phonological. It derives from the interaction of ALIGNWORD (#φ) and ALIGNFEET (φφ#) yielding the *initial dactyl effect*: #(Øσ)σ(Øσ)(Øσ)#. Like primary stress, secondary stress is sensitive to syllabic weight, which results in the avoidance of heavy-final feet.

¹⁴ The causative *-ña* 'CAUS' can be considered an exception, as its two vocalic allo-morphs *--en* and *--an* yield diphthong-final verbs.

Grammar lattice, final iteration.

4.7 FURTHER RESEARCH

In this section, a tentative observation will be made about the phonological status of the glottal stop in A'ingae. Namely, it is possible to analyze the glottal stop as a suprasegmental feature, rather than a segmental phoneme. Possible motivations for this analysis will be listed here, but its potential implications are left to future research.

Many of the features of glottal stops discussed in the preceding chapters point to their suprasegmental status in the language.

First, glottal stops can be, and often are, realized as creaky voice. When the glottal stop is realized as creak, the creakiness can extend across multiple syllables in accord with what could be expected of a non-segmental feature (see [Section 2.5](#)).

Second, glottal stops show a very close affinity to stress (see [Section 4.5.1](#)). They appear only in the head constituent, attract stress, and are essentially culminative, since there can be at most one glottal stop per word. These features suggest an analogy with systems of pitch accent, many of which have the same properties.

Third, a plethora of the language's functional morphemes begin with glottal stops, giving rise to most of the language's glottal minimal pairs (see Sections [3.1](#) and [4.5](#)). This brings to mind the category of floating tones known from morphologically-rich tonal languages.

Fourth, glottal stops appear in the coda position, although A'ingae otherwise prohibits codas (see [Section 2.4](#)). This suggests that the glottal stop is not a proper coda, and might be better analyzed as a feature of the nucleus, analogous to other suprasegmentals.

Fifth, the position in which the glottal stop can surface is greatly restricted. At the level of the syllable, the glottal stop is limited to the coda (see [Section 4.5](#)). At the level of a verbal root, the glottal stop is restricted to the penultimate syllable (see a footnote on page [77](#)).

Combining the two limitations on the glottal stop's syllable-wise and stem-wise distribution, it can be seen that in any verbal root of the shape [σσ] or [σσσ], the position of the glottal stop is fully predictable: [σ?σ] and [σσ?σ]. This is to say: in a verbal root, the glottal stop is always right before the last syllable. This suggests that its position is underspecified and points to its suprasegmental character. For another analysis of the glottal stop as suprasegmental with respect to the verbal root, see Silva ([2016](#))'s work on Desano.

Although nothing in the current proposal conflicts with a reanalysis of glottal stops as a suprasegmental feature and some aspects of it, such as ALIGNGLOTTAL (Hd?), actually invite it, full implications of this idea are to be explored in future research.

5

CONCLUSIONS

To do.

A.2 SYMBOLS

	MEANING
,	set member separator
{ }	set of alternatives
*	markedness
-	affix boundary
=	clitic boundary
≈	ambiguous clitic boundary
/ /	underlying form boundaries
[]	surface form boundaries
?	glottal stop
—	heavy syllable
~	light syllable

MEANING	
μ	mora
σ	syllable
φ	metrical foot or structure
ω	prosodic word
()	metrical foot boundaries
[]	morphological stem boundaries
# #	(lexical) word boundaries
$\langle \rangle$	unparsed constituent boundaries
Hd	head constituent
σ	syllabic head of a word
δ	syllabic head of a foot
\times	strong beat
.	weak beat
Dp	dependence
Mx	maximality
\neg	antifaithfulness
\gg	constraint domination
,	undetermined ranking
{ }	set of constraints
*	constraint violation
!	fatal violation
—	constraint irrelevance
	optimal candidate
φ	cophonological function
o	phonological level o
1	phonological level 1
\times	suffix dominance
:	construction-specific ranking
$>$	construction succession

A.3 GRAMMAR SIGNATURE

MAXIMALITY(STRESS), or $Mx\acute{\sigma}$
 Stress is not deleted.

NONFINALITY, or $*\acute{\sigma}\#$
 The final syllable of a word is not its prosodic head.

ALIGN(?, R, WDHD, R), or $Hd?$
 Glottal stops are final in a prosodic head of the word.

MAXIMALITY(?), or $Mx?$
 Glottal stops are not deleted.

FOOTSHAPE, or $(\times\mu)$
 Feet are trochees, whose right branches are monomoraic.

DEPENDENCE(STRUCTURE), or $D_P\varphi$
 Metrical structure is not epenthesized.

ALIGN(PrWD, L, Ft, L), or $\#\varphi$
 A foot is word-initial.

ALIGN(Ft, R, PrWD, R), or $\varphi\varphi\#$
 Feet are word-final.

ANTIMAXIMALITY(STRESS), or $\neg Mx\acute{\sigma}$
 Stress is deleted.

ALIGN(STEM, R, STRESS, R), or $\acute{\sigma}]$
 The stem-final syllable is the prosodic head of the word.

LEXICALWORD≈PROSODICWORD, or $\#\omega\#$
 Every lexical word corresponds to a prosodic word.

PARSESYLLABLES, or $*\langle\sigma\rangle$
 All syllables are parsed by feet.

Operative constraints.

VOICE / VALENCE	ASP	MOT	NUM	MOD	POL	TAX	TOP	FOC	ILL	PER
